For many years it has been known to histologists that the specific end-organs of taste, namely, the taste-bulbs, occur on the posterior or inner surface of the epiglottis, but up till now the physiological proof of the existence of the sense of taste in the epiglottis has not been forthcoming. Michelson<sup>2</sup> under Langendorff's direction, made a number of experiments, which show that the inner surface of the epiglottis is endowed with taste. A Schroetter's laryngeal sound tipped with a solution of quinine or saccharin, was introduced into the larynx, and the drop of the sapid substance was cautiously brought into contact with the inner surface of the epiglottis. Positive results were obtained, which were controlled by the sensation — electrical taste — known to be produced by electrical stimulation. It seems, therefore, proved that a part of the nerve fibres passing to the larynx are nerves of taste.

#### THE USE OF THE FLESH OF POISONED ANIMALS.

This subject has been studied by Schmidt-Mülheim with a view to determine whether if eaten by men such flesh would be injurious.<sup>3</sup> As reported in the *Revista Internazionale d'Igiene*, of Naples, for June, 1891, it may be used without any danger whatever. Many savage races constantly use the flesh of the animals that have been killed with poisoned weapons, and have never been injured by that means.

Harnus has proved that the flesh of animals that have been poisoned with nux vomica and with tartar-

<sup>1</sup> British Medical Journal, August 8th.

<sup>2</sup> Virchow's Archiv. III, 3, 1891.

<sup>3</sup> Sanitarium, August.

ized antimony is not at all hurtful; Feser has demonstrated the same fact in regard to strychnine and eserine; Spallanzani, Zappi, and Sonnenschein have done the same for arsenic.

Froehner and Knudson have made some experiments for this purpose with strychnine and with eserine. They fed dogs with large quantities of mutton poisoned with strychnine and eserine, and they found that no injury whatever was done to the animals. Besides, they themselves eat some of the poisoned meat and drank soup made from it, and found that the flavor was good and had no injurious effects whatever on the system.

In regard to the alleged injurious effects caused by the meat of animals poisoned with hellebore, and which had eaten belladonna leaves, the authors have shown that the accounts published in this regard have not been proved and require further tests.

The *Revista* says that in the interest of meat inspection, it is desirable that experiments should be made with other poisons.

## Correspondence.

### DR. ANDREW D. WHITE'S WARFARE OF SCIENCE.

NABANT, August 28, 1891.

MR. EDITOR:—Though I might regard the great bitterness of Dr. White's reply to my criticisms as to some extent a tribute to their justice, I am sorry that the discussion should have become such a personal one. I regret it the more because the fault in this respect was chiefly mine. My purpose is now to review very briefly the main points of the discussion, and see to what extent I have proved my charges of great inaccuracy.

First, as to the School of Salerno. It is some twelve years since I looked up the matter, and I was not acquainted with the more recent studies which have since appeared. It seems that I was wrong to ascribe its foundation to the Benedictines; for the truth is that next to nothing is known certainly of its origin. This being so, I would ask, Why did President White state that its creation is largely due to Jewish scholars? I must beg leave to point out that I said that his statement that this school was held in aversion by multitudes of strict churchmen, was unlikely but not impossible. I did not say it was a gross misrepresentation, as in his reply he says I did.

Next, as to the decree of the Fourth Council of the Lateran, Dr. White made the statement that physicians were forbidden to undertake medical treatment without calling in ecclesiastical advice, under pain of excommunication. I pointed out that they were commanded merely to advise the patient to call in a confessor. To my astonishment, in his reply Dr. White reiterates the charge that the latter was called to treat the body, and talks of "pastoral medicine," "the little wax *Agnus Dei*," "St. Remy's ring," etc. To show that all this is quite imaginary I must summarize the essential parts of the decree. It states that as bodily infirmity sometimes arises from sin (in which by the way I can see no inherent absurdity) physicians of the body should, first of all, warn and induce their patients to call the physicians of the soul, "so that after provision has been made for the sick man's spiritual welfare, there may more wholesomely follow the remedy of bodily medicine, since when the cause ceases the effect ceases." Now, be it noticed that once I called the physician of bodies and the other the physician of souls, and that there is not a word in support of Dr. White's statement that the priest was to do

anything for the good of the patient except to administer the sacrament. There is not a shadow of evidence that he was to use what Dr. White so politely calls fetiches. But to return to the decree. It continues that one reason for its passage is that sometimes patients, when advised to attend to their souls, fall into despair, and thus run greater danger of dying. It is clear that if this advice is always given the patient will not be alarmed by it. I think I am quite justified in saying that Dr. White gave a false impression. As to the penalty, he admits that I am partly right, but not wholly, because he says that prohibition to enter a church is not a very different thing from excommunication, but rather the first step towards it if the offender does not repent. I would reply that in those days excommunication was a terrible penalty, the other perhaps the mildest ecclesiastical censure. It is not canon law that one led necessarily to the other, even if there were no reform. I do not deny that it must have been unpleasant; but there was no reason for incurring the penalty. I may add, moreover, that though the offender made himself liable to this penalty, it does not appear that it was incurred *ipso facto*.

Now as to the prohibition to advise anything for the good of the body that might be injurious to the soul, I consider it most salutary. That even saints and theologians held views which now strike us as peculiar, is quite irrelevant. The order is not to do what is sinful for health. Dr. White's reference to the *Corpus Juris* is so inadequate that I have not been able to verify his quotation from St. Gregory. It makes little difference; for even a saint and a pope writing on matters of faith and morals is not infallible unless he makes the declaration *ex cathedra*. Dr. White's implication is on a par with his statement made elsewhere in these papers that another pope "ordered the world under pain of damnation" to believe the miracles of St. Francis Xavier.

We shall consider together the alleged prohibition of dissection and the case of Vesalius. Dr. White wrote that Boniface VIII interdicted dissection as sacrilege. This is both a serious and a definite charge. I have shown that he forbade only the eviscerating and boiling the dead that their bones might be brought home. Dr. White is kind enough to say "that in a small, technical way," I am correct, but that the decree really was directed against dissections, though it did not say so. He asks me what I suppose Boniface's motives to be. If he will turn to the document he will find that it is tacitly implied that the custom was common among nobles and prominent people. It was not a decent way of treating the body; it shocked people. Does any one doubt that it would shock people now? The decree goes on to direct that the bodies are to be left where they are till they be reduced to dust, and that then they be transported. The penalty seems excessive to me as well as to my adversary, but I presume the Pope knew better than we what penalty was necessary to break up the custom. The argument that because this forbade a method of moving bodies, by so much the more it forbids dissection, is ingenious but nothing else. Why, in the name of common sense, if the Pope wanted to forbid dissection, did he not say so? What was there to deter him? If it were true that all authorities of note have held that this view was levelled at all dissections, it only would show how loosely history is written.

President White, however, has cited a high authority, which he appears to have since forgotten. The following passage is from his own paper concerning Vesalius's career: "A conference of divines having been asked to decide whether dissection of the human body is sacrilege, gave a decision in the negative. The reason was simple. The great emperor, Charles V. had made Vesalius his physician, and could not spare him." This is a typical example of Dr. White's historical methods. To support his theory, he says, in effect, that this council of divines gave a false decision to please the emperor,—a charmingly simple explanation. I wonder if it has yet occurred to him that it is just possible that the council reported as it did because it was true. It is very hard to reconcile such

<sup>1</sup> Popular Science Monthly, May, 1891, p. 47. Dr. Payne writes of the school and who discussing its foundation. "The Jewish element appear to have been important among the students, and possibly among the professors."

<sup>2</sup> Popular Science Monthly, June, 1891, p. 156.

a passage as the one just quoted with the author's boast that he has never warped history.

I must admit that there is weight in Dr. White's argument that a man offensive to Rome might therefore be honored by Venice. Unfortunately, I am not enough of an historian to decide just how much weight it has in this particular case. Whatever Vesalius's troubles may have been, dissection, pure and simple, was not their cause.

I do not remember that Fallopius, his successor, was ever disturbed. True, he was at Padua; but Eustachius, one of the most renowned dissectors of the day, was professor at Rome itself. Finally, to come to the cause of the journey to Jerusalem, which cost Vesalius his life, I find that Hæser, whom I had not consulted for years, till after Dr. White's reply, treats the stories of ecclesiastical persecution as fables. Is it too much to ask that Dr. White should give us the definite statement of some unimpeachable authority in support of his views?

Yours truly,

THOMAS DWIGHT, M.D.

### UNEQUAL PUPILS.

UNALASKA, ALASKA, August 4, 1891.

MR. EDITOR:—The subjoined instance recently came within my observation. It is presented in the hope that wider experience may explain what seems anomalous.

The patient is a robust man, aged thirty years. The history of the case does not give any certain cause, though he had severe headaches when about six years old. The condition was first noticed near twelve years of age. The eyes are both hazel in color. The right pupil is habitually twice the size of the left. Vision in the right eye is somewhat less clearly defined than in the left during the day or in the light. Vision in the left eye is a trifle less clearly defined than in the right during the night or in the dark. Otherwise, visual power is good in both eyes. No astigmatism. Pupils react to eserine, atropine, light and darkness.

Very truly yours,

F. B. STEPHENSON, Surgeon, U. S. N.

### PLEURITIC EFFUSIONS.

FREDERICTON, NEW BRUNSWICK, August 27, 1891.

MR. EDITOR:—In reading your valuable Journal of the issue of August 20th, my attention was directed to an article on Acute Pleurisy, by Dr. Perry, of Jamaica Plain, in which, in the closing sentence, he speaks of the amount of effusion removed at one aspiration (129 fluid ounces) as the largest within the experience of several gentlemen.

On August 20th, there called at my office for the first time, a young man, apparently twenty-five years of age, five feet ten inches in height, about 140 pounds weight, slender in build, anæmic and short of breath, who told me that he had had an attack of pleurisy about ten months ago. His physician removed a small quantity of serous fluid at that time, and a few months later, in the Massachusetts Hospital, Dr. Shattuck removed about one pint.

On examination, found whole right chest, front and back, completely flat from base to apex of lung. No respiratory sounds. The heart apex was displaced to the left about two and one-half inches. On measurement, there was but little difference between right and left chests on the mammary line, but lower down, right chest was one and one-half inches larger.

On the 22d, with Codman & Shurtleff's aspirator, removed fourteen pints (wine measure) of pus. This would mean 224 fluid ounces. The fluid was emptied into the pint measure as the bottle filled, and, a tally being kept by myself, the result showed the number of pints above mentioned.

The patient, who had remarkable pluck, exhibited somewhat alarming symptoms toward the close of the aspiration, becoming more pallid, with small flickering pulse and

great pain in expanding lung. Hypodermic morphia (one-third of a grain) was given, with good effect.

He drove five miles on the 24th, two days later, to see me at my office.

No doubt a permanent drainage-opening will be required before very long.

Yours sincerely,

G. E. COULTHARD, M.D. (Harv.).

### METEOROLOGICAL RECORD.

Peabody	10,158	2	—	—	—	—	—	—	

Deaths reported 2,852: under five years of age 1,327; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 800, consumption 288, acute lung diseases 135, diarrhœal diseases

586, diphtheria and croup 92, typhoid fever 84, scarlet fever 27, whooping-cough 29, malarial fever 30, cerebro-spinal meningitis 16, erysipelas 6.

From scarlet fever New York 10, Chicago 6, Cleveland 4, Brooklyn 3, Cincinnati 2, Baltimore and Lawrence 1 each. From whooping-cough New York 9, Baltimore 3, Brooklyn and Boston 2 each, Chicago, New Orleans, Cleveland and Milwaukee 1 each. From malarial fever New York and Brooklyn 5 each, New Orleans 9, Baltimore 1. From cerebro-spinal meningitis Chicago and Worcester 3 each, Brooklyn, Baltimore and Lynn 2 each, New York, Cleveland, Lowell and New Bedford 1 each. From measles New York 5, Chicago 3, Brooklyn 1. From erysipelas New York, Chicago, New Orleans, Cleveland, Milwaukee and Nashville 1 each.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,405,108, for the week ending August 15th, the death-rate was 18.8. Deaths reported 3,385; acute diseases of the respiratory organs (London) 185, diarrhoea 382, whooping-cough 96, measles 39, diphtheria 34, fever 26, scarlet fever 24.

The death-rates ranged from 12.1 in Derby to 28.5 in Portsmouth, Birmingham 14.9, Bradford 16.6, Hull 15.3, Leeds 21.0, Leicester 18.3, Liverpool 21.1, London 20.1, Manchester 19.4, Nottingham 14.2, Sheffield 16.2, Sunderland 24.2, Wolverhampton 15.9.

In Edinburgh 14.4, Glasgow 20.0, Dublin 22.8.

#### OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 22, 1891, TO AUGUST 28, 1891.

Major VALERY HAVARD, surgeon U. S. Army, granted three months' leave of absence, to take effect on or about September 5, 1891.

Captain M. C. WYETH, assistant surgeon U. S. Army, sick leave of absence, extended three months on surgeon's certificate of disability.

Captain JAMES E. PILCHER, assistant surgeon U. S. Army, is relieved from duty at Fort Clark, Texas, on expiration of leave absence, and is assigned to duty at Fort Ringgold, Texas.

#### OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING AUGUST 28, 1891.

P. A. HESLER, passed assistant surgeon, detached from U. S. S. "Pensacola" and to the "Charleston."

#### CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

##### SECOND TRIENNIAL SESSION.

The Congress meets in Washington, D. C., September 22d to 25th, inclusive. It is composed of the members of the National Medical Societies, and of foreign guests specially invited by the Executive Committee. To enable a physician residing in the United States to become a member of the Congress, with the right to participate in its proceedings, it is necessary that he be a member of one of the Constituent National Societies. A physician may be accredited as a visitor to the Congress by any one of the Constituent Societies. The certificate of the Secretary of one of these Societies to the effect that he is thus accredited will enable him to register upon payment of the registration fee, which registration will entitle him to a card of admission to the President's reception and to a copy of the Transactions of the Congress, but not to take part in the deliberations of the Congress.

All physicians are invited to attend the meetings of the Congress, and the public meetings of the societies, but only those who register who are members, specially-invited guests, or visitors accredited through the Secretaries of Constituent Societies.

The registration office will be in parlors 1 and 2 of the Arlington Hotel. From this office the mail of members and invited guests will be distributed, and here the city address of each member, and of accredited visitor can be ascertained. All members, invited guests, and accredited visitors should register as soon as possible.

A fee of one dollar will be required of all members and accredited visitors. Invited foreign guests will register, but will pay no registration fee. A copy of the published Transactions of the Congress will be sent to all members, and to each invited guest and accredited visitor who registered. Only those who register, and the ladies accompanying them, will be admitted to the reception of the President of the Congress. It is recommended that members effect registration in

advance of the meeting by filling out the blank certificates of registration which will be sent to each member about September 10th, and forwarding these certificates, with the requisite fee, to Dr. John S. Billings, Treasurer of the Congress.

The sessions of the Congress will be held from 3 to 6 p. m., daily, in the main hall of the Grand Army Building, 1412 and 1414 Pennsylvania Avenue.

The President of the Congress, Dr. S. Weir Mitchell, of Philadelphia, will deliver an address Wednesday evening, September 23d, at 8 p. m., "On the History of Instrumental Precision in Medicine."

Members of the American Surgical Association and of the Association of American Physicians will conjointly entertain their foreign guests at a dinner at the Arlington Hotel, Thursday, September 24th, at 8 p. m.

Other Societies will give dinners as follows: Thursday evening, Gynecological, Orthopedic, Laryngological, Pediatric, Neurological. Tuesday, Dermatological and Andrology and Syphilology. Date not yet decided, Climatological.

For particulars of reduced railroad fares see page 201 of the JOURNAL of August 20th.

As other societies will meet in this city during the Congress week, it will be prudent for members and visitors to secure hotel accommodation in advance. The Arlington Hotel offers accommodations at the rate of four dollars per day, and the Hotel Arno at three and four dollars a day on the American plan, or one dollar a day per room only, on the European plan. The Committee will take pleasure in answering any inquiry relating to the local arrangements of the Congress.

*Officers of the Congress.*—President, S. Weir Mitchell, M.D. Vice-Presidents, ex-officio, Presidents of Constituent Societies. Chairman of Executive Committee, William Pepper, M.D., Philadelphia, Pa.; Treasurer, John S. Billings, M.D., Washington, D. C.; Secretary, William H. Carnath, M.D., New Haven, Conn.; Samuel C. Busey, M.D., Chairman, Committee of Arrangements, 1545 I Street, S. W., Washington, D. C.

#### DEATHS.

ROBERT T. GODFREY, M.D., of Montreal, died August 23d, aged 73.

THOMAS PRATT, M.D., died August 29th, at the University Hospital, in London. Dr. Pratt, twenty years ago, was one of the most distinguished American physicians in Europe. He was the son-in-law of Dr. Marion Sims. He served in the Confederate army as surgeon during the Civil War, and on the German side in the Franco-Prussian War. After the German victory he lived in Paris, and fifteen years ago went to London, where he has since resided. During recent years he has been an invalid.

ABRAHAM DE BOIS, M.D., died in New York, August 29th, aged 81 years. He was born at Red Hook, Dutchess County, N. Y. In 1845 he was appointed assistant surgeon of the New York Eye and Ear Infirmary. He held in this institution successively the places of surgeon, consulting surgeon, secretary of trustees and vice-president, during forty-eight years of service. He held at the time of his death several offices; among them that of consulting surgeon to the New York Institution for the Blind, consulting physician to the Northern Dispensary and to the Home for Incurables. He was also a member of numerous charitable associations in New York. He was for many years medical director of the Manhattan Life Insurance Company.

Mental Suggestion. By Dr. J. Schorowicz, Professor of Psychology in the University of Leuberg. Translated from the French by J. Fitzgerald, M.A. In four parts. New York: The Hammond Publishing Co. 1891.

Minor Surgery and Bandaging, including the Treatment of Fractures and Dislocations, Tracheotomy, Intubation of the Larynx, Ligations of Arteries and Amputations. By Henry R. Wharton, M.D. Demonstrator of Surgery in the University of Pennsylvania. Illustrated. Philadelphia: Lea Brothers & Co. 1891.

## Address.

COMMON SENSE IN MEDICINE.<sup>1</sup>

BY S. C. GORDON, M.D., PORTLAND, ME.

(Concluded from No. 10, page 236.)

In a paper read before the American Medical Association at the last meeting, by Dr. McKee, of Cincinnati, he makes the following statement: "The vast majority of medical students, in America, graduate without ever having witnessed a case of labor. Until within the last three or four years, the majority probably equalled ninety-nine per cent." In surgery, of course, it is equally bad. Rarely is it given to a student to try his "prentice hand" upon the living human being until he begins the race of professional life for himself. Too many, by far, have never even seen enough to become familiar with the ordinary instruments. Surgery is largely mechanical,—an art, to be acquired only by manual labor, so to speak. You may fill a man full of the theory of surgery, and unless he has seen the actual work, or tried with his own hands, the art of surgery will remain a lost art, so far as he is concerned. To begin to be a surgeon one must first learn by ocular inspection the difference between normal and abnormal structures, normal and abnormal organs. To be able to decide what nature can do, and what ordinary therapeutics can do, and, what is of equal importance, what they cannot do, is essential to a correct diagnosis and prognosis. A celebrated surgeon once said that a surgical operation was a confession of failure to cure. To decide promptly and execute without unnecessary delay, marks the brilliant surgeon.

All this must come through clinical experience. To execute skilfully, early in professional life, implies long experience in the use of instruments either by dissections or operations upon the cadaver. A familiarity with ordinary mechanic's tools, which may be acquired in boyhood and early manhood, is a good preparation for the use of surgical instruments. One of the most skilful operators in this country served his apprenticeship as a machinist.

I think every one who has seen Dr. Tait operate will readily admit that he is *facile princeps* in his skill and celerity. The manual dexterity he evinces is simply something miraculous. Of his own methods of learning the surgical "craft," he says, "I served my time at the lathe, the bench and the forge." He further says, "Upon one point we are coming to an agreement, and that is a demand for a restoration of the apprentice system. While the student is attending to this most important part of his training, he ought at the same time—and I am now speaking for those who have to follow the craft of surgery—to be taught how to use his hands. I should set him so many hours in the week into the shop of the village carpenter, and I should have him trained to use a saw, a chisel, a plane and a skew, so that he should be able to make a long splint, if need be, as well as to put it on. And into the blacksmith shop he should go until he is able to strike properly with a hammer." He thinks "a training in practical mechanics as necessary for a man who is to operate upon his fellow human beings, as is a training in anatomy." All of this is

the veriest common sense in comparison with the majority of medical teaching, the veriest *uncommon* sense.

While the fundamental principles of the science of medicine and surgery are and can be taught from books, to a certain extent, yet I repeat that which I said many years ago, in a report to this association, "that no man can afford to study medicine now, unless he makes clinical instruction the important part of such study, and as counsellors of the student we are bound to impress this upon him accordingly. To my mind it is the key-note to modern medical education. 'Things and not words' (which are only the representations of things) convey most lasting impression. We must see the patient with our own eyes, hear with our own ears, and touch with our own fingers. Knowledge gained in this way ever remains, while the acquisition does not in the least interfere with the necessary study of books."

With a proper medical education comes the more practical question, "What are the essential elements of success in practice?" First and most important, I should say, is a capacity for work, and a willingness to do it,—work for work's sake, for the love of it, regardless of the immediate recompense. Unless the young man just entering the profession is willing, at all times and under all circumstances, to do any and every kind of professional work that may come to hand, he can never expect, neither has he any right to expect, success. Any case, however simple, or however poor or humble the patient, develops something, either in experience or another case. The former is most needed at this period in one's career. The young man who shows this willingness to work, for work's sake, is not usually long without something to do, neither is he long before he knows how to do it. The older men in the profession are soon to find out who are the drones among the young men; and it is an extremely simple question, who are the men to call upon whenever duties are to be delegated, or whenever advice is sought in reference to such young men. I have never had any sympathy for, or patience with, the young professional man who fails to improve any and every opportunity to acquaint himself with the every-day work of his life, simply because he could not see an immediate pecuniary recompense.

The clinical advantages of a hospital so situated as to be accessible daily, should be eagerly sought and duly appreciated as a valuable aid to success, especially in the matter of familiarity with surgical diagnosis and technique. I fear young men too often neglect even such obvious means of instruction. In European medical centres we find every hospital appointment, however humble, filled by the young and rising men in the profession; years of work are readily given before any position of importance can be obtained; vacancies are always filled from the willing workers. While "kissing goes by favor," to some extent, in our country, it is getting to be more and more a matter of merit every year.

I am aware that one's personality counts for much towards a true success. Each man must work out for himself the problem, and must, therefore, in all the relations of life, maintain an individuality which shall preserve him from losing his honest convictions. In a republic like ours each man has a personal interest in all that relates to the affairs of the nation, and, as a citizen, should exercise all his political rights in a free and independent manner. While the physician can-

<sup>1</sup> Annual oration delivered before the Maine Medical Association, June 10, 1891.

not of necessity mingle in the details of political strife, he should have intelligent convictions on all political questions, and be ever ready to maintain and defend them, and identify himself fully and heartily with the political party that is in harmony with his convictions, whether it be Democratic or Republican. All honest men respect honest difference of opinion on politics or religion; all honest people equally despise hypocrites in either. These are sacred, individual rights, and no true man can afford to sacrifice either of them for any temporary expediency. While they are entirely independent of professional education and practice, yet one's professional work is more or less influenced by habits of thought and action on other matters. Clear, definite views on secular matters can come only from logical reasoning on the facts presented; and just as we examine these subjects, will we, to a great extent, examine medical subjects. I should fear that the doctor who never gave an unqualified opinion on any of the important questions of the day, would become doubtful on any and all professional questions. I would say, therefore, to all young men in the profession, Give no uncertain sound on questions of a character which concerns you as an individual or the interests of the country or community in which you live. Act intelligently, but act — promptly if necessary, but act.

"To thine own self be true . . .  
Then canst thou not be false to any man."

The field of medicine is by no means fully cultivated, and there is abundant room for new workers. A man must ever keep his mind free for new truths; and in order to do this, he must do his own thinking, without blindly following any man or theory which seems at plain variance with common sense. Medical literature is full of fashions and fads which had their day, and were relegated to the rubbish heaps as "back numbers." A glance at a few of them may not be without profit at this time. Among the text books of my early professional study the antiphlogistic system of treating inflammation had the prominent place. My childhood recollections are full of instances of excessive blood-letting by venesection, active cathartics, alternative doses of calomel and antimony, *ad nauseam*, etc. My early professional life was the reaction from this, so that it required undaunted courage to open a vein. I am sure we carried the reform too far — the pendulum swung to the opposite extreme. In my opinion blood-letting is one of our most valuable remedies when judiciously used, even by venesection, while cups and leeches have ever held a prominent place in my own practice. In all local, circumscribed inflammation, nothing can take the place of them. I have never regretted blood-letting, either by general or local means, but have often regretted I had not bled more.

Mr. Tait has revolutionized the medical world by salines in peritonitis. All this appeals to our common sense, and all now wonder how we could have been bound down by the opium splint of Alonzo Clark so long. I feel sure we have not yet seen the full benefit of this mode of treatment. I have been satisfied for two years that peritonitis arising from the cecum and appendix should be treated heroically by salines, without regard to the cause. The condition is what immediately demands our attention. The cause has done all the harm it can, when we are first called. A free depletion will relieve the congested and inflamed vessel, preventing, in a majority of cases, suppuration

and gangrene, thus allowing the case to terminate by resolution. If abscess result, then operate, and drain with the least possible disturbance to the tissues. If the appendix can be reached, remove it; otherwise leave it. I feel that the theory of early operative interference is untenable, provided we follow the saline plan. It is the plainest common sense, to my mind.

I am well aware that precedents weigh much with the ordinary practitioner; and the young man feels bound to keep in line with what he is taught. He feels, at least, that he must have given all the remedies that are advised, otherwise he cannot stand well with the consultant. Could I impress upon the young practitioner one thing more than another, it is this: never give medicine unless you are fully convinced that you can give a reason for it. I mean this to be the general principle of action. Do not cheat yourself by any delusion that the patient must have medicine or he will think you are doing nothing. Once you have established a reputation for prescribing only when needed, and you have a lasting hold upon the people who are worth having. It may require a little longer, but it is time well spent. Trust Nature when she is doing well. My admission to the homœopathic system of medicine is that in nine cases out of ten of acute disease the patient will recover by natural processes if we nurse and nourish well, without a drop or grain of drugs. Within a few years I have seen a case of typhoid fever where the attending physician had eleven different drugs in the sick-room, all of which had been used in the case within a few days. The delirium, high temperature, diarrhœa, etc., yielded rapidly under the influence of small doses of Seidlitz powders, frequently repeated, as a substitute for powders, pills and potions. I fully believe in therapeutics; but my theory is, the simpler the better. The stomach must be humored, and its right of ejection at least, be respected. "Letting severely alone" is more strictly in accordance with common sense. I also as fully believe that the rights of the stomach, so far as the demands for food and drink are concerned, are as much entitled to respect. I do not believe that we are wiser than Nature in this particular. I have rarely seen the patient for whom I could make a diet list, in entire opposition to the natural cravings of his appetite. There is no common sense in attempting it.

In all such matters as this each man must judge for himself, and have the courage of his convictions, derived from his own observation and experience. Follow no man's dictum contrary to your own good judgment; otherwise you become mere imitators, "baffled by every wind of doctrine."

"To break new ground is still one of the uncommon and most heroic of the virtues," says one of the brightest of our American novelists. This is so true in our profession, that it needs no illustration, and yet the profession is full of examples. An equally uncommon and heroic virtue is to courageously acknowledge one's failures, when breaking new ground is not a success. If we are willing to say we do not know, when we are ignorant, publish our bad cases as well as our good ones, we are not only having the courage of our convictions, but we are benefiting every one. The best minds of the world and the best teachers in our profession have been the most courageous in this latter respect.

Professor Conheim says, "I anticipate the time when physicians will more and more regard fever, not

as a condition free from danger, but on the whole as a wise provision of Nature; not as a storm to be controlled by antipyretics, but as a ship to be guided by safe routes, by natural methods, until the storm is past."

Holmes believed that it would be (on the whole) better if all drugs were poured into the sea, than given in the blind, unthinking way they are. To be sure, he pitied the fishes. This was an exaggerated statement, but such men as he and Jackson did much to stay the empirical administration of medicine, so prevalent at that time.

Homans, as a surgeon, has deserved much from the profession, for his frankness and minuteness of detail in his published cases.

Thomas, as a teacher, does not hesitate to admit that many pet theories of his own, have been laid by on the shelf as useless.

Mr. Tait, in a recent paper, admits that there are many cases requiring removal of the uterine appendages, for nervous symptoms alone. His former teaching has been contrary to this. I do not quote his exact language, but simply the substance. He is a man of strong conviction, but his immense experience and broad views have taught him that there is a common-sense association of symptoms and cause; that errors of diagnosis, in this class of cases, have been made, I have no doubt; but that is no fault of the theory.

No man has shown more frankness in acknowledging what he believes to be errors than Mr. Lister. No one has received more criticism, or borne it more cheerfully. The chief point upon which he has been most severely criticised, was that of the use of chemicals in the form of spray into the fresh wounds, with a view to their effect upon the surrounding atmosphere and the noxious germs contained therein. Some of the best men in the profession, throughout the civilized world, honestly and frankly believed and taught that not only were the germs contained in the atmosphere harmless but that a spray of 1 to 40 of carbolic acid, must of necessity be harmful and poisonous. Instances of poisoning were abundant in the current literature of the day, and the opponents of the system declared honestly that such a plan was contrary to common sense, and useless. The fact that open wounds of the face and other parts, difficult to cover and usually clean, healed so promptly was an argument adduced. Yet the spray was insisted upon as a *sine qua non* in surgery.

Read what Mr. Lister says in his address at the last International Medical Congress at Berlin, last August: "As regards the spray, I feel ashamed that I should have ever recommended it for the purpose of destroying the microbes of the air." He goes still further when he says, "And yet I must confess that I have for a long time doubted whether either the washing or the irrigation is really necessary. These doubts have been raised partly by experiments, some of which I mentioned at the London Congress, which had proved to me that normal blood and even pus, were by no means favorable soil for the growth of microbes, in the form in which they are present in the air." This expression of Mr. Lister is that of an honest man, endowed with common sense, and voiced the sentiment of a large number of equally honest, common-sense men, who had opposed the irrigation of fresh wounds by chemicals of a destructive and toxic character. His more modern and simpler asepsis appeals

at once to the common sense of all of us, while antiseptics for septic cavities and surfaces, every one approves and uses.

The most wonderful, brilliant meteor that has appeared in the medical sky in our day and generation is certainly the theory advanced by Koch on the cure of tuberculosis. Already its brightness has dimmed; and I believe not many months will elapse ere it will sink in oblivion, and be remembered only as one of the delusions of medical lore. It did not stand from the first as a common-sense method, but the honesty and scientific ability of its originator gave us much to hope.

Having thus briefly touched upon some of the more prominent elements of success in the practice of the profession of medicine, our time will not allow a further discussion as to many other things so essential to the making an ideal physician and surgeon. We must ever remember that there is no royal road to success, in this or any other calling; that there is no mysterious methods in legitimate study; but that by long and patient labor in the lines suggested, a young man who seriously begins his course may reach to almost any point in professional eminence that has ever been attained.

It is an old and very trite saying, that "Genius is simply an infinite capacity for taking pains," which, translated into the language of our theme, means the application of common sense to our every-day life-work.

I cannot better close this paper than by a quotation from an article from the pen of one of London's best writers and investigators, Dr. B. W. Richardson: "Twenty years ago we were steering well and steadily toward great principles on the preventive as well as the curative side of medicine. Then there crept in the wild enthusiasm for bacteriological research,—research good enough in its way, as a piece of natural history, and as disclosing some curious vital phenomena developed under morbid states of the organic structures and the blood, but a positive insanity when accepted as the one absorbing pursuit, restoring the humoral pathology, ignoring nervous function, leading to Babel with its utter confusion of tongues, and separating for a time our modern art of cure from the accumulating treasures of knowledge, wisdom and light of over two thousand years."

### PRODROMAL AND EARLY SYMPTOMS OF BRIGHT'S DISEASE.<sup>1</sup>

BY CHARLES F. WITHINGTON, M.D., OF ROXBURY.

No feature of chronic nephritis, more especially in the interstitial variety of the disease, is more startling than its insidiousness. A man generally supposed to be in good health is suddenly stricken with convulsions, and the urinary examination, then for the first time made, shows renal degeneration to be extensive, inveterate and irremediable. Or the autopsy-table is the first revealer of the chronically contracted kidney, whose slow changes have for years, all unconsciously to its possessor and to his family, been undermining the citadel of life.

<sup>1</sup> Read before the Massachusetts Medical Society, June 9, 1891, and recommended for publication by the Society.

Even the careful medical examiner, with his suspicions aroused, may fail to detect the fatally advancing disease, by urinary examination. Dr. H. C. Wood<sup>2</sup> has published a number of cases in which he says the urine was absolutely normal, so far as his tests could go, and yet advanced cirrhosis of the kidney was present. Flint also insists that the urine of renal cirrhosis is sometimes perfectly normal. Fortunately we may, I think, believe that instances are rare in which interstitial disease fails to betray itself, if examinations are careful and repeated. Yet the experience of these writers, not lacking the support of other authorities, as to the elusiveness of the physical signs of this affection in some instances, may well make us seek for all possible means, in obscure cases, of confirming our evidence.

The class of persons most obnoxious to chronic (interstitial) nephritis, hurried and overworked business men, in the height of their activities and responsibilities, are not introspective. They are not symptom-hunters, and so long as their bodies answer reasonably well to the exacting demands which they make upon them, these men make no complaints. Hence early symptoms, which persons of the other sex or of different temperament would speak about, are unnoticed or ignored.

What are the prodromal or at least the early symptoms, significant of this affection, which should arouse the physician's suspicions and put him on the track of a diagnosis? Such symptoms may, as I have said, be *nil*, or they may be of such a slight and vague character as to point to nothing more serious than digestive disturbance or the result of fatigue. But they will bear the closest study.

Without at the present time going into any discussion of the vexed questions regarding the pathogeny of this disease, and looking upon the subject chiefly in a clinical light, we may, I think, put foremost among the prodromata of chronic interstitial nephritis, some manifestation of *gout*. It may be latent; it may show itself by no more patent sign than lithuria. This connection is generally admitted, though we may not go so far as to say with Tyson that gout is always, sooner or later, followed by interstitial nephritis. That statement is of course to be taken subject to the limitation that the patient must be spared from intercurrent diseases long enough to complete the evolution of his nephritis. A gentleman now under my care with lithuria, a trace of albumen and hyaline and finely granular casts, tells me that 46 years ago he had what was diagnosed by a prominent Boston physician as gout, though he has never had any arthritic symptoms of the disease since. I have been able to trace a similar connection in more than half my patients either to arthritic gout or to "gravel."

It may be remarked in passing that Virchow,<sup>3</sup> who disputes the currently-believed relation between uric acid calculi and gout, nevertheless admits the frequent infiltration of urates in various parts of the body, including the kidney, in persons suffering from latent gout, and thinks that both the renal changes and the joint affections are due to the urates loading the blood.

Danforth<sup>4</sup> has recently sketched graphically the development of early pathological changes in the kidney due to irritating substances in the urine, among

the first of which he places uric acid. To a less degree he finds oxaluria and phosphaturia sources of irritation to the tubular epithelium and so of renal inadequacy.

Less intimate as a diathetic antecedent of nephritis than gout, is rheumatism. It not infrequently happens that a rheumatic attack serves to *declare* a contracted kidney. The patient fails to rally well from his rheumatism, and examination reveals an interstitial nephritis, which in some instances doubtless may have antedated the rheumatism.

The growing importance attached to chemical factors in the aetiology of disease (with the discovery of poisons and other noxious chemical products of microbic life) and the apparent relation above referred to between uric acid, as a chemical irritant, and the production of renal changes, suggest the inquiry whether other chemical poisons, such as lead and arsenic, which Dr. Putnam has shown us are so frequently detectable in the urine, may not stand in some relation to Bright's disease. If, as one may believe, gout has a kinship on the one side with lead poisoning and on the other with nephritis, it seems not unreasonable that its two congeners might sometimes have a direct communication with each other.

Sir Andrew Clark has described a "renal inadequacy," which he thinks is perhaps a very early stage of Bright's disease, where there is as yet no visible alteration of structure, but where a healthy secretion cannot be produced.<sup>5</sup> The urine is a little scant, has a low specific gravity and is deficient in urea. Such patients take cold easily, and in the event of an acute illness or of a surgical operation, do badly. A restriction of the diet, the author says, increases the urea elimination and the health of the patient. A strong objection to this view has been raised in the query, How, if the kidney is "inadequate" to the secretion of a normal amount of urea, can the reduction of the diet, with the diminution of the material out of which urea could be obtained, possibly increase that product?

The line of demarcation between prodromal and early symptoms of Bright's disease can probably never be sharply drawn. Just when, for instance, lithæmia passes over into the graver affection we may not know. But all persons who have finally died of interstitial nephritis have at some time passed over that (or some other equally) shadowy line. Could it have been known when they were approaching it, treatment then might have been of some avail. Of the symptoms of the early stages of pronounced Bright's disease, some, as will be seen, are far from distinctive. But when they are grouped with others, in themselves no more characteristic, the combination acquires a greater significance.

In classifying the symptoms of Bright's disease one is tempted to use as a basis the various pathological processes which have been recognized as marking the evolution of the disease, as for instance hydraemic plethora, increased vascular tension, endarteritis and vascular degeneration, and finally so-called uræmia. But this classification seems to me unsatisfactory, because, first, many symptoms would come under more than one of these classes. For instance, headache may be produced by increased vascular tension, hydraemia or anæmia. It may come from a degenerated cerebral vessel and be the precursor of an apoplexy, or it may be a "uræmic" symptom. Hemorrhages are favored, on the one hand, by vascular degeneration, on the

<sup>2</sup> Boston Med. and Surg. Journal, vol. cxli, p. 19.  
<sup>3</sup> *Berliner Klin. Wochenschrift*, 1881, No. 1, and *London Medical Record*, November, 1881.

<sup>4</sup> *Transactions Association American Physicians*, vol. v, p. 257.

<sup>5</sup> *British Medical Jour.*, February 24, 1885, p. 315.

other by increased arterial tension. But again, there is not at present any agreement as to what is the primary pathological change, or in what order the others develop. So-called uræmic symptoms are almost certainly not due to retained urea, and are by many referred to vascular changes involving disturbances of circulation. They often are among the earliest instead of the latest symptoms, sometimes occurring in the prealbuminuric stage.

I therefore submit the following list of clinical symptoms, arranged not according to theoretical processes but to organs involved.

SYMPTOMS.	
<i>Brain.</i>	{ Irritability, depression,
Headache.	{ Weakness of mind,
Mental states.	{ Delirium,
	{ Insanity.
Disorders of sleep.	{ Sopor,
	{ Sleeplessness,
	{ Night-terrors.
Motor.	{ Staggering,
	{ Convulsions,
	{ Paralysis,
Sensory.	{ Neuralgias,
	{ Paræsthesias,
	{ Dizziness.
Coma.	
<i>Digestive.</i>	{ Vomiting,
	{ Dyspepsia,
	{ Diarrhoea,
	{ Constipation, etc.
<i>Circulatory.</i>	{ Anæmia,
	{ Increased tension, palpitation, angina,
	{ Oedema.
Hæmorrhages.	{ Epistaxis,
	{ Retinitis,
	{ Hemoptysis,
	{ Apoplexies.
Polyuria.	{ Frequent micturition,
	{ Nocturnal enuresis.
<i>Respiratory.</i>	{ Cough, expectoration,
	{ Dyspnoea, Orthopnoea,
	{ Cheyne-Stokes breathing,
	{ Asthma.
Oedemas.	{ Glottis,
	{ Pleura,
	{ Lung.

The limits of this paper do not of course admit of the discussion of these symptoms in detail. I will merely touch upon one or two, hoping that others will be elucidated in the discussion.

The mental states in Bright's disease are particularly interesting. Early in the affection patients sometimes complain that "the head feels muddy." There is a slight haze over the intelligence which the patient himself is aware of. The soundness of the business judgment may be impaired. Irritability, petulance or depression and moroseness are noted by the friends. The patient becomes a little self-distrustful and possibly somewhat secretive about his affairs and intentions. He shows unusual annoyance, for example, at the loud playing of the organ in church, at street noises, at the importunity of a peddler, etc. He dislikes to reckon or to play cards unless the simplest game, and soon tires of that. He falls asleep by day or perhaps lies awake at night. Suddenly comes an attack of acute delirium, with delusions which in the case that I have just been describing was followed by a series of eclamptic attacks. With recovery from these the delusions disappeared, and the mental state returned to nearly the condition before the active delirium.

The insanity of Bright's is recognized among alienists, not as a distinct type of mental disease, but as of ætiological peculiarity. Dr. Alice Bennett gave an

address last year as president of a section of the Pennsylvania Medical Society,<sup>6</sup> upon "Uræmic Poisoning as one of the most frequent causes of Insanity." She described some twelve cases rapidly fatal, in from twelve to ninety days; as many less rapidly fatal (three months to nine and one-half years), eight of rapid and three of slow recovery, and other groups which remained stationary or pursued a very slow downward course.

Dyspnoea is a symptom, which, as will appear later, is one of the most frequent and earliest of Bright's disease. When there is any organic affection of the respiratory organs, as bronchitis, asthma, œdema, or of the heart, the symptom appears very natural. But when there is no structural alteration other than perhaps left ventricular hypertrophy, it is much less easy to explain. This dyspnoea may be continuous or paroxysmal, in the latter form amounting to intense orthopnoea with a sense of asphyxiation. Dr. E. P. Howard,<sup>7</sup> of Montreal, suggests that the continuous dyspnoea may be due to diminution in the number and oxygen-absorbing capacity of the red blood globules, so that the respiration is taxed to furnish the increased oxygen thereby necessitated. As for the paroxysmal dyspnoea, commonly classed as a symptom of uræmia, the mechanism of its production has not been, so far as I know, satisfactorily explained.

In the hope of determining something of the relative frequency of the earlier symptoms of chronic nephritis, I have taken off the data from 100 cases, chosen somewhat at random from the earlier record-volumes of the Nervous and Renal Service of the Boston City Hospital. These cases were all diagnosed as chronic Bright's, but the variety was not as a rule, specified. The great frequency of œdema as a symptom, seems to make it probable that the prevailing type of the disease was the diffuse or parenchymatous, rather than the interstitial, which detracts from the value of the figures for our present purpose. The minuteness of the early symptom-record depends of course much upon the habit of the clinical recorder, and in these cases the first recorded symptoms range from twenty years to a fortnight before the admission of the patient. In a hospital, of course, patients are not admitted until some positively disabling phase of the disease is present, and their ability at that time to recall the first symptoms of their illness is not always to be depended upon.

Of these 100 persons, then, with "Chronic Bright's," the following numbers had experienced, prior to entering the hospital, the symptoms severally set down against them, which are arranged in the order of frequency:

Œdema	42
Dyspnoea	42
Nausea and vomiting	39
Frequent micturition and polyuria	34
Cough	23
Headache	20
Rheumatism	18
Pain in small of back	14
Blurred sight	11
Vertigo	10
Palpitation	10
Dyspepsia	8
Neuralgia	7
Weakness	7
Hemiplegia	6

<sup>6</sup> Transactions Medical Society of the State of Pennsylvania, vol. xxi, p. 127.  
<sup>7</sup> Canada Medical and Surgical Journal, November, 1881, p. 193.

Syncope and falling . . . . .	4
Malaria and bilious fever . . . . .	3
Diarrhoea . . . . .	3
Pain in right hypochondrium . . . . .	3
Jaundice . . . . .	3
Convulsions . . . . .	2
Epistaxis . . . . .	2
Insan. ty, sleeplessness, numbness, itching and tremor, each . . . . .	1

In just one-half these cases are the habits as regards alcohol recorded; and of these 50, 23 used alcohol (the amount not stated), 12 used much liquor, 5 used no liquor.

With a view of studying the evolution of symptoms in the most insidious form of chronic nephritis, I again had recourse to the City Hospital records, this time taking as the starting-point the post-mortem diagnosis of chronic interstitial nephritis. For this purpose, aided in part by the painstaking autopsy-index prepared by Dr. Prescott, I went over the first twelve volumes of autopsy records, covering the years 1873 to 1890, selecting only those cases in which well-marked interstitial disease of the kidney was established by the autopsy. From these I eliminated all surgical cases. Nineteen other cases were rejected in which the patient was brought to the hospital comatose or practically moribund, so that no adequate history of his previous condition was obtainable. Of these 19 patients, 1 may say in passing, 4 died of convulsions, 4 of hemiplegia, 1 of pneumonia, and the rest in coma.

I have tabulated the remaining cases, 75 in number, of persons dying from, or at least with, chronic interstitial nephritis. Of these, 49 were males, 26 females. The average age was nearly 17.4 years. Twelve of these persons had died of intercurrent affections, that is, diseases not directly connected with the pathological processes of Bright's disease: 7 of pneumonia, 3 of cancer, 1 of meningitis, and 1 of tuberculosis. Subtracting these cases, as possibly incomplete, through having ended prematurely, I find that nevertheless, the remaining 63 uncomplicated cases of Bright's died at exactly the same average age as the whole number, namely, 17.4 years.

Studying the 75 tabulated cases more closely, we learn that 23, or 31%, had suffered from rheumatism. Many of them had had repeated attacks extending over many years; one, for instance, 20, another 30, another 35 years. Four gave a previous history of malaria.

The habits regarding the use of alcohol were recorded as affirmative or moderate in the case of 12, excessive in 10, and abstinent in the case of 4.

In seeking to establish the relative priority or sequence of symptoms, one must be on his guard against placing too much dependence on mathematical averages. The dates which are set down in the tables are computed backward in each case from the time of the patient's death. Often, of course, these dates are lacking, and in proportion to this defect and to the wide departure of any one individual in a small class from the others, the value of averages is impaired. With this preliminary caution, I will enumerate the symptoms in the apparent order of their priority.

1. Polyuria, with frequent micturition, and especially increased nocturnal micturition, was experienced by 26 persons, or 33%; one had it 20 years before death, and 1 for 2 years and over. Eight persons gave no date on this point, showed an average of 4 years of polyuria before death. This average does

not, as some others will be seen to do, require to be raised to represent the true figure.

2. Dyspnoea was experienced by 47, or 61%, being the most frequent symptom. The longest case was 40 years. The average of 26 persons giving dates, was 108 weeks, or a little over 2 years. But this average requires to be materially raised, from the fact that it does not include 4 persons who had had dyspnoea for "years" and 1 who had had it "always." So that the true average date of dyspnoea should be carried back nearer to that of polyuria.

3. Edema, observed in 38 cases, or 51%. (This will be remembered in comparison with the 84% of oedema in the mixed cases of chronic Bright's.) The longest cases were 15 and 12 years. The average of 29 persons was 69 weeks, which requires to be slightly raised on account of a 30th person who had had it for "years."

4. Cough occurred in 41 persons, or 56%. The longest 10 years; 2 for 5 years. The average of 32 persons, 47 weeks, which is somewhat too low, as there were three others who had had it for "years."

5 (or 6). Palpitation, 19 persons, or 25%. The average of 9 persons had had it for 26½ weeks, which is a little too low, as it does not include one person who had had it for "years."

6 (or 5). Headache, 20 persons, 27%. Two had had it "always" and one for "years," which should materially raise the average of 11 others who had had it for 21 weeks.

The remaining symptoms average too near each other and are based on too small a number of cases to warrant an opinion on their relative priority.

Nausea and vomiting, present in 37 patients, or 49%. One had had vomiting "always," one for "years," and 24 others averaged 9½ weeks before death. This average is probably too low.

Amblyopia, in 11 persons, or 15%. One person had had it 7 years. Including him in 6 cases giving dates, we should have an average of 54 weeks; omitting him 5 cases give 16 weeks, which is doubtless nearer right.

Vertigo, in 13, or 17%. The earliest 22 weeks; the average of 5, 9 weeks.

Diarrhoea, in 16, or 21%. One had it for 10 years. The average of 10 others, 6.2 weeks. (Per contra, 3 record constipation.)

Lumbar pain, in 4 persons, 5%; which shows the popular fallacy of back-ache as a symptom of Bright's, at least in this form.

Cerebral hemorrhage occurred in 10 persons, or 13%. The earliest was 5 years before death. Three had 2 attacks, and 1 had 3. Six died from hemorrhage of brain, or meninges.

Other hemorrhages occurred as follows: of the nose, 7; of the lungs, 6; bowels, 2; stomach, 1.

Delirium occurred in 15, or 20%. It was generally a late symptom, the earliest case being 3 months, and 11 cases appearing first within the last two weeks of life.

Disorders of sleep are thus classed: insomnia or vigil in 11; drowsiness or sopor in 4. Rather a late symptom.

Convulsions, of course, occur late. They are recorded in only 7, or 9%. Coma, prior to the day of dissolution, in 26. Cyanosis is spoken of in 11 cases; in at least 5 it was noted 10 days or more before death.

Of other symptoms, infrequent, but of significance,

## HALLUCINATIONS IN THE INSANE.<sup>1</sup>

BY EDWARD B. LANE, M.D.,  
*Assistant Physician to the Boston Lunatic Hospital.*

HALLUCINATIONS and kindred phenomena have, from the earliest times, made a profound impression on the human mind. They have awakened man's sense of awe and stimulated his curiosity. They have appealed to his fears and nourished his egotism. As is well known, they have contributed, in no small measure, to various religious beliefs, and they have exerted an influence in the affairs of nations. In recent times, hallucinations, like many other phenomena, have been subjected to critical study by the faithless materialism of our day, with the result that we are asked to regard all such as due to morbid cerebral action. This belief is, however, far from being universally adopted at present. The majority of people are yet inclined to look upon a vision as something uncanny, and prefer to believe the hallucinated as holding some occult relation to the supernatural world ; unless, indeed, there is reason to believe one experiencing an hallucination to be insane. Fortunately to-day the spiritual theory of mental disease is all but obsolete. While men are willing to allow that hallucinations of the insane are subjective and pathological, they cling to the belief that hallucinations in the sane are a source of revelation from the spiritual world.

It is certain, however, that hallucinations of the senses are capable of being explained in physiological terms ; also that they are a frequent symptom of various forms of mental disease, and in one form (paranoia), at least, it would appear that they are a constant symptom.

Yet, no one will deny that hallucinations occur independently of mental disease ; although we may not call an hallucination physiological. How frequently they occur in the sane I am sorry to say I cannot tell. The census that is now being taken in this country has not been sufficiently analyzed. It will show probably that not far from ten per cent. of the adult population have had, at least, one hallucination. Whatever the result may be I think it will prove to be a surprisingly large one — allowing *liberally* for errors necessary to such a faulty method of collecting statistics.

For several years I have observed the acute cases of insanity coming under my notice, with especial reference to the presence or absence of hallucinations. It is the statistical results of such analysis that I have ventured to present to you to-night. I shall await with much interest the analysis of the census of hallucinations among the sane. Perhaps not until they are published will the results of the small number presented here be of much significance.

It is not my purpose to discuss the nature or origin of hallucinations, whether in the sane or insane — but by way of explanation, I will simply state that I regard all hallucinations as the result of perverted action of the sensory regions of the cerebral cortex — thus closely allied to the function of memory and the phenomena of dreams.

The almost inevitable result of an hallucination, whether in a sane or insane person, is a delusion. This will not be an *insane* delusion necessarily. Such delusions are, first, an explanation of the false perception itself and this explanation varies with the past experience of the individual, his education and beliefs — secondly, in the insane, delusions regarding the supposed author of the apparition or voice.

The writer has long had a theory that the prevalence of hallucinations in the sane explained the growth of the delusion (as he regards it) of spiritualism in this community.

There is a large clientele of victims of occasional false hearing, or false sight, who grasp with eagerness any explanation of their experience which coincides with their previous education, and, at the same time, tends to increase their own importance.

It is customary in hospitals to speak of a patient becoming insane through spiritualism. I prefer to believe that spiritualism is the result of hallucinations, and that insanity would have been very likely to occur even though the theory of spiritualism had not been previously accepted.

The relation of hallucinations to delusions is a very intimate one, and is very important in the study of insanity. Delusions are found in the insane who have not experienced hallucinations — more especially is this true in acute mania and general paralysis, for in these diseases the characteristic delusions are less apt to be based on hallucinations. In paranoia, on the other hand, the delusions are, in most cases, the direct outcome of hallucinations. In many cases of melancholia, also, the depression is increased by the hallucinations, though both hallucinations and delusions are secondary to the sense of depression. In this affection, however, the hallucinations appear to give rise to a great variety of secondary or superimposed delusions.

While this paper is devoted to the subject of hallucinations it is necessary to explain that I have found great difficulty, practically, in differentiating hallucinations and illusions in the insane. Clearly marked illusions I found rather rare. Yet, in the case of certain senses, it must be admitted that it is almost impossible to say that a given experience is not an illusion. We can verify the patient's story when he claims to see a face in the dark or hear the voices when all is quiet. But, if he says he felt a hand, it is clearly impossible for the observer to be sure there was no external irritation. This difficulty obtains as well in the senses of smell and taste. The patient says he tastes arsenic in his food. He is eating, and various substances are being perceived by their smell and taste. Still more is this true of visceral hallucinations, as we cannot assert the patient may not be subject to various sensations which he misinterprets.

Because of the impossibility of accurately distinguishing illusions from hallucinations I have considered them all as hallucinations.

Physiologically, the two symptoms are so much alike I think the distinction a very unimportant one in this connection. Yet the few cases where the trouble was clearly illusions of sight and hearing, unaccompanied by hallucinations, have not been considered in the statistics presented.

Nor have I attempted to tabulate all the cases of insanity seen. The cases presented are a small fraction of those seen by me, but believing a few hundred cases carefully analyzed would be much more valuable

<sup>1</sup> Read before the Boston Medico-Psychological Society, March 13, 1891.

for statistics than a larger number poorly studied, I have limited myself to those cases where I could get a fair history, or have observed the case long enough myself to make a diagnosis. I have also rejected many doubtful cases. As shown by the table presented I have rejected all cases of secondary delusional insanity and secondary dementia, for various reasons, chiefly because the acute forms of mental disease are more profitable to study, and the secondary conditions are in no proper sense forms of mental disease, no more than the wrecks along the beach are to be classed as a special form of ocean craft.

As shown by the table the total number of cases studied is 307.

## PARANOIA.

Out of 67 cases of paranoia there were none who did not at some time have hallucinations, and in only three of this number were hallucinations of hearing not found. In one of these cases hallucinations of sight and of smell or taste were very constant. He was inclined to talk much about his delusions, but I never could get any evidence of hallucinations of hearing, and I think it very doubtful if he had them. In the other two I cannot feel sure that they may not have existed and were not noticed. Neither of these cases were inclined to talk about themselves.

It would appear from this that not only are hallucinations to be expected in all cases of paranoia, but that the absence of auditory hallucinations is rare. I have heard old asylum attendants say that false hearing was a bad sign. I think this observation due to the bad prognosis in paranoia, and the more or less

continuous presence of this symptom during the course of this disease.

Hallucinations of hearing unaccompanied by those of the other senses, occurred in 38 cases, or considerably more than half. Hallucinations of sight and hearing in 19 cases—and also in five more cases in which hallucinations of smell (or taste) were present in addition.

In one case there were hallucinations of sight alone. In one case only hallucinations of smell or taste occurred alone. In two cases hallucinations of hearing were accompanied by tactile and visceral hallucinations or illusions.

To summarize—Hallucinations of one sense only were noted in forty cases; of two or more senses, in twenty-seven cases.

## ACUTE MELANCHOLIA.

Out of 55 cases of acute melancholia (excluding simple melancholia) in 50, or a little more than 90 per cent. were hallucinations a symptom. Here, as in paranoia, hallucinations of hearing preponderate, for in only five of the 50 hallucinated cases did they fail to be noted. In 18 cases there were hallucinations of sight, in five of which this symptom occurred alone, in the others with false hearing. In four cases three senses were involved; namely, sight, hearing and smell or taste. In no case did I note hallucinations of smell or taste alone.

## ACUTE MANIA.

In acute mania, hallucinations were less frequent than in the two diseases just considered. Out of 38 cases, 20, or a little more than half, gave no evidence of hallucinations. In the 18 cases where they were found, those of hearing were present in every one; in three cases hallucinations of sight occurred as well. Other senses were not affected.

## GENERAL PARALYSIS.

This symptom was present in 15 out of 34 cases of general paralysis.

Hallucinations of hearing are again more frequent, being present in 12 cases (in nine alone, in three with visual). Those of sight were noted in five cases, and of smell or taste in only one, and then without those of other senses. In these rather few cases hallucinations were not a continuous symptom, but appeared transiently and rather in the first stage.

## OTHER DISEASES.

Hallucinations were present in three of ten cases of post-paralytic insanity, and in all of six other cases of organic brain disease. Grouping them together we find this symptom in nine of 16 cases; auditory in eight, and visual in six. In one of these cases was noticed what is unique in this series, hallucinations of four senses: namely, hearing, sight, smell and touch. This series includes eleven cases of insanity of pubescence, in six of which hallucinations of hearing were observed, and in two of the latter those of sight occurred also.

In considering epilepsy I have not tabulated all the epileptics seen in the hospitals, but have taken merely those cases in which there was decided mental alienation. Out of 14 such cases hallucinations were present in eight. In these few cases hallucinations of more than one sense in the same case were not found. Four cases had auditory, and four visual, hallucinations.

Hallucinations of hearing were present in all the four cases of katatonia, two of which had visual hallucinations as well.

I fear my experience in hysterical insanity has been exceptional, as I have noted hallucinations as present in only one of six cases. In this case there were both visual and auditory hallucinations.

There are 29 cases tabulated as senile insanity. Here rather less than half (namely 13), experienced hallucinations. Eight of these had auditory, and seven visual, hallucinations. As will be seen the two forms of hallucination occurred together in two instances.

In classifying this series of cases, three cases were found in which the mental disturbance was so clearly due to alcoholic excess, and the cases could not easily be put in any other group here mentioned, that I have called them alcoholic insanity. As was to be expected, they all had hallucinations. More than this, all three had hallucinations of sight, — two had auditory as well, and one of them complained of various visceral sensations in addition.

In order to determine what part, if any, abuse of alcohol played in causing hallucinations in mental disease, aside from delirium tremens, I have grouped for study those cases in this series where there was marked alcoholic excess. There are eighteen such in addition to the three mentioned. Out of these 21 cases, in only four were there no hallucinations. Of the 17 cases where the symptom was present, only two failed to have false hearing, and they had visual hallucination. Nine had auditory hallucinations alone; six had auditory and visual, of whom three had olfactory as well. I am aware the cases are too few from which to draw valuable deductions. But, as far as they go, they fail to show that hallucinations are much more common in alcoholic subjects. But it does appear that visual hallucinations are relatively more frequent in alcoholic cases.

There are four cases of recurrent mania, a periodic insanity, one of the degenerative psychoses, — hence they are not included under the head of acute mania; only one of these had hallucinations. Only one case of folie du doute appears. Hallucinations of hearing were present. Twenty-five cases yet remain to be examined. In these no hallucinations were observed. They are classified as: Two cases simple mania; 10 cases simple melancholia; 7 cases folie circulaire; 6 cases senile dementia. Thus, taking cases as they come from this series, it appears that 63.87% have at some time hallucinations of some sense, and 36.13% have no hallucinations.

Excluding the diseases in which we found no hallucinations, let us consider the 282 cases of diseases in which hallucinations may be expected to occur.

Hallucinations present . . .	No. Cases.	Per Cent.
" absent . . .	196	70
" of hearing . . .	86	30
" of other senses without auditory halluc. . .	175	62
" of sight . . .	21	8
" of smell or taste . . .	77	27.3
" of touch . . .	13	4.6
" of viscera . . .	4	1.5
" of sense of equilibrium, . .	9	3.2*
	3	1*

\* This symptom is not indicated in the table, as it would have made it unduly complicated. The cases in which they occurred, however, are all tabulated as hallucinations of other sorts occurred in them.

There are nine cases in which anomalous visceral sensations were complained of, which I believe to be analogous to hallucinations. It must be admitted, however, that such cases are often found to have serious lesions, which may give rise to unusual sensations. For example, a woman who claimed to feel a number of animals (ferrets, worms and leeches) in her body, was found to have a bony tumor on the ileum.

In three cases, at least, there appeared to be an hallucination of the sense of equilibrium. I have seen this in one other case, not included in this series. While it might be claimed that the sensation of vertigo, not caused by a previous oscillation or rotation of the body, was strictly an hallucination of the sense of equilibrium, the examples referred to me do not refer to the feeling of vertigo, strictly speaking. One of them, to use her own words, complained of a spinning sensation. I have suspected this condition to exist in the case of an epileptic patient, who, several times when delirious, believed himself to be aboard a moving train. In the case not included in the three tabulated here, a man had the delusion he was aboard ship, but he confessed to feeling the motion of the vessel. It is remarkable that this disturbance is not much more frequent, as it is so very common in our dreams, — almost universal, I should say, — to experience the feeling of falling rapidly just before waking.

In one case only have I noted what might be an hallucination of the muscular sense. In this case a man complained that his arm felt tired in the morning from the weight of his wife (who had been dead for some time). But as this is capable of another explanation, I do not care to cite it as a clear case of muscular hallucination.

Tamburini has recently published several very interesting cases of hallucination of the muscular sense. It is now all but universally admitted by psychologists that there is a muscular sense. If so, why may we not find hallucinations of such a sense? The cases reported by Ségas and Tamburini are, without question, to be considered muscular hallucinations. It is an interesting fact, that in all their cases the hallucinations were referred to the vocalizing organs. So, too, in the vast majority of auditory hallucinations, it is "voices" that are heard.

It appears that it is these sensory images most used in thought that are most likely to be revived as hallucinations during perverted cerebral action.

From a study of the subject of aphasia it appeared to the writer that the majority of men think in auditory rather than other images. It would be out of place to present the reasons for this conclusion here; but I desire to call attention to what appears to me to be a very significant fact. The preponderance of hallucinations of the sense of hearing over those of other senses is due, I believe, to more than accident. It is due to the physiological law of thought, if I may be allowed the term. As a rule, we are inclined to think in auditory images. Certainly the child who has not learned to talk, but understands what is said to him, must think in auditory images so far as names go. This early training must do much toward forming a habit of thought in auditory images; and by the usual methods of instruction other images acquired in the use of language are superimposed on the auditory.

In this connection it is interesting to note that the commonest answer received to the questions sent out for the census of hallucinations is, "I heard my name

called." And although I have not analyzed these cases with reference to the matter of the hallucination, and have therefore no figures, my impression that hearing the name called, or being "called out of one's name," as our Irish patients say, are the commonest experiences with the insane.

If an hallucination be simply the revival of a past sensory impression, why may we not have an hallucination of a painful sensation? This is almost impossible to affirm in a given case; but I can see no reason, *a priori*, why such an hallucination may not exist. A feeling of pain referred to an amputated member need not be regarded as an hallucination, however, for an irritation of the stump might cause a true pain, which by an error of judgment would be associated with the lost part.

I was interested in Dr. Prince's paper, read before the Society this winter, on the subject of hysterical pains. He offered an explanation that they were due to an association process. If I understood him, it would seem as though that were an hallucination, the idea or memory of pain being so thoroughly recalled as to make the patient project the sensation to the affected part. Unfortunately, pain is purely subjective, and we can but theorize on its reality when claimed by others.

In studying the table presented, it is evident that the ratio of auditory to visual hallucinations varies considerably in different diseases. It occurred to me to contrast two groups with reference to this point. In the first group let us put mania melancholia and paranoia, a total of 160 cases. In this group we find auditory hallucinations in 127, or 79 per cent. of cases, and visual in 47 cases, or 29 per cent. In the second group let us put these diseases where we would expect more gross anatomical lesions, namely, general paralysis, organic brain disease, epilepsy and alcoholic insanity, — making a total of 61 cases. Here we find auditory hallucinations in 26 cases or 41 per cent., and visual in 18 cases or 22 per cent. Thus while there appears to be a falling off of visual hallucinations there is a much greater one in the auditory; and in the latter group visual hallucinations are (relative to the auditory symptom) much more frequent.

Does not the fact that auditory hallucinations are more frequent in the psychoses than in organic brain disease lend support to the view that auditory images are more necessary to thought than others? On assuming this view to be the true one and reasoning *a priori*, ought we not to expect that auditory images would be more readily aroused in these diseases where perverted mental action was an important feature? And in those diseases following coarser organic lesions might we not expect the various sensory regions to be more equally irritated and senses other than the auditory to be represented in hallucinations.

It would be interesting to compare such statistics with similar ones as regards dreaming.

The distinction between hallucinations and pseudo-hallucinations has been made recently. I need not explain that the latter refers to those hallucinations whose subjective character is recognized by the percipient.

A pseudo-hallucination is much less apt to be followed by delusions and insanity, the question is at once suggested might not a previous education in the subject of hallucinations, illusions, etc., prevent in many cases the serious consequences of hallucinations now seen in many uneducated people.

I believe there are a considerable number of cases sent to asylums yearly where the whole trouble is based on the continuation of the distressing symptom of false hearing; which cases would under proper care — if they had previously been taught that such experiences are very common — have made a rapid recovery at home. On the other hand, I know there are cases where pseudo-hallucinations persist so long, and are so disgusting or harassing that the patient in time becomes a victim of melancholia. Nor is it likely that the degenerative psychoses would be affected permanently by the knowledge that hallucinations are subjective.

### SHOCK FROM AN ELECTRIC WIRE.

BY F. W. JACKSON, M.D., WESTON, MASS.

P. R., of Weston, age twenty-two, weight 150 lbs., a well-developed, muscular fellow, while driving home from Waltham, Saturday night, August 3d, had an encounter with a "live electric-light wire." His horse's feet became entangled in a wire that had broken away from its pole connection and fallen across the street.

The horse finally extricated himself from the wire, and in so doing removed some of the insulating material, in sections of one inch, — two or three in all. R., in his attempts to remove the wire, probably seized it at one of the unprotected points, thus forming a perfect circuit. He was immediately thrown a distance of ten feet against the curb-stone, and then instantly to the middle of the street again, swaying back and forth three times. His hands were in contact with the wire about three minutes, when, from some unknown cause, the current suddenly broke, and he dropped to the ground unconscious, remaining so about ten minutes, then in a semi-conscious state fifteen minutes, after which was removed to my office.

I first saw him two hours after accident. Pulse 100, strong and bounding; temperature 100°; pupils dilated; headache; nervous and irritable; reflexes increased. Headache accompanied by insomnia continued for three days, after which time rapidly disappeared, and he resumed his work as railroad section-hand without any inconvenience, apparently none the worse from the shock. The palmar surfaces of both hands and arms were blackened from tips of fingers to a point midway between wrists and elbows, and were sensitive to touch, and on the least irritation the muscles would violently contract — disappearing on the second day.

Two days after accident the company's agent effected a settlement with him, which did in no way modify the convalescence, as he was totally ignorant of the results of coming in contact with a "live electric-wire," or electricity in any form.

The current was from a fifty-light Thomson-Houston arc machine, ampère current 6.8; the voltage was about 2,100 on that circuit at that time, it being a new three-braided electric-light wire, did not consequently allow the electric current to escape through. It being a wet night and raining heavily at the time, was undoubtedly the cause of his sustaining such a severe shock. The voltage passing through his body is wholly problematical; and it is my opinion that, had he been

acquainted with electrical appliances and the power of electricity, the shock would have been more severe and lasting, possibly terminating fatally. Treatment: quiet, rest, bromide potash.

## Medical Progress.

### RECENT PROGRESS IN OPHTHALMOLOGY.

BY MYLES STANDISH, M.D., OF BOSTON.

#### NUTRITION OF THE LENS, AND THE FORMATION OF CATARACT.

MAGNUS,<sup>1</sup> in an experimental study of nutrition of the lens and the formation of cataract by the means of saturation with grape sugar, naphthalin, or salt, draws the following conclusions concerning the nutrition of the normal lens:

(1) The nutritive processes are more active on the posterior than on the anterior half of the lens. This conclusion agrees with the observations of Deutschmann, who, in rabbits killed three hours after receiving a dose of iodide of potassium, found the iodide in the lens chiefly in the posterior sub-capsular layers. It agrees also with the clinical observations of Fuchs, who has noted that it is only in the posterior cortex that any considerable clearing up of traumatic opacity ever takes place.

(2) The chief nutrient stream enters the lens in a zone which lies parallel with and immediately behind the equator.

(3) A less important nutrient stream enters the lens in the zone lying immediately in front of the equator.

(4) The posterior pole also receives a nutrient stream, which is, however, of smaller amount than those entering the equatorial zones.

(5) The anterior pole appears to receive no nutrient stream from without.

(6) The equator itself receives no direct stream, but depends for its nutrition on the zones lying immediately before and behind it.

#### SIMPLE EXTRACTION OF CATARACT.

Greef,<sup>2</sup> in a report of 450 simple extractions of senile cataract in Professor Schweigger's University Eye Clinic, says that the extraction of senile cataract without iridectomy has so far obtained less of a foothold in Germany than in France, England and America; less, in fact, than it has actually deserved.

The operations were done under aseptic precautions, which included the cleansing of the skin around the eye with ether, as well as bathing both the upper and lower everted eyelids thoroughly with 1 to 5000 sublimatesolution. The incision was made with the Beer's knife, partly with a downward flap entirely in the corneal tissue, and partly with an upward flap made in the same manner. If a prolapse occurs, if small, it may be safely left to itself; but if large, should be abscised in order to get rid of the astigmatism which it invariably excites.

The cases of loss embrace nearly five per cent. of the entire number. With regard to the prolapse of the iris, it is the opinion of our author that injuries after the

operation are the most frequent causes, and that in this class must be included many cases in which the patient will not acknowledge that he has received any injury; it happens over and over again that, taking advantage of the absence of the nurse, the patient will leave his bed for some fancied reason and, not seeing anything, will easily run against obstacles of various sorts. In one case there was a prolapse of the iris in the patient, who bent over towards the floor on the second day, after getting out of bed against the strictest orders. Many patients will press upon the bandage violently with the thumbs. Where better care is taken and the patients are more reasonable, as in private clinics, prolapse of the iris is not found so frequent. Prolapse of the iris from traumatism through the section once already cicatrized, is rare after the fourth day; yet it occurred in one of these cases in a rather full-blooded woman, while bending over during a bath on the twelfth day.

Prolapse of the vitreous is one of the chief anatomical conditions that leads to prolapse of the iris, and when it may be expected, therefore, in high degrees of myopia, fluidity of the vitreous, etc., the operation iridectomy should be done. As to whether the prolapse of the iris is oftener seen after the upward or downward section, our author states that these cases offered no evidence one way or the other.

During the first cases eserine was used after the operation, as well as on the evening of the same day; but it was soon discovered that there was no need of it, and for that reason it was abandoned. It does not prevent prolapse of the iris, whilst it undeniably favors the formation of posterior adhesions. In Schweigger's clinic, much more care is taken in the first few hours after the new operation than the old. The patient must remain as quiet as possible for three full days, and the bandage is renewed on the second day, but the eye is not inspected. The eye is opened on the third or fourth day, and from thence onward atropine is instilled till the pupil remains of sufficient width.

#### SIMPLE EXTRACTION OF CATARACT.

Bull<sup>3</sup> sums up the advantages of a simple extraction as follows:

(1) If successful and without complication, it preserves the natural appearance of the eye, a central, circular and movable pupil.

(2) The acuteness of vision, with the astigmatism carefully corrected, is somewhat greater than after the old operation.

(3) Eccentric vision and orientation are decidedly better than by the old operation.

(4) Small particles of capsule are much less likely to be incarcerated in the wound, and thus act as foreign bodies and excite irritation.

(5) It is a shorter operation in point of time, by reason of the absence of an iridectomy.

(6) As there is no iridectomy, there is little or no hemorrhage, and this may be considered a very decided advantage.

#### THE OPERATIVE TREATMENT OF HIGH MYOPIA BY EXTRACTION OF THE LENS.

Fukala<sup>4</sup> reports twenty-three cases in which he has operated on myopic eyes by repeated discissions; this being done in many instances as often as fifteen times,

<sup>1</sup> Van Graefe's Archiv., vol. xxxvi, 4, p. 150.

<sup>2</sup> Archives of Ophthalmology, vol. xx, No. 3, p. 303.

<sup>3</sup> Transactions of the American Ophthalmological Society, 1890.

<sup>4</sup> Arch. f. Ophth., xxxvi, 2, p. 230.

and the results, as given in this report, are certainly encouraging. The oldest patient was twenty-four; the youngest eight; the myopia in all cases was as high as eleven dioptres, and in some as high as twenty dioptres. Only those with good visual acuity (J. 1) and free from choroidal or retinal disease were thus treated. In a small number of the cases an upward iridectomy was done before the lens was needed. The vision for distance was very much improved in all cases.

#### PSEUDO-MEMBRANOUS CONJUNCTIVITIS.

Fage,<sup>6</sup> in a short paper, records a case of conjunctivitis with formation of membrane, in which search was made by careful bacteriological investigations to solve the problem of the identity or non-identity of this form of disease and true diphtheritic conjunctivitis. The condition which was described by von Graefe as diphtheria of the conjunctiva, is of frequent occurrence in North Germany, but according to Fage, is rarely met with in France.

A membranous conjunctivitis does occur in the latter country, however, which was first described by Bouisson in 1846; but is not considered as really diphtheritic. In the form described by von Graefe, the cornea generally suffers and is often partially destroyed; but in the form described by Bouisson, although a definite false membrane is found on the palpebral conjunctiva, it is far less malignant, and usually disappears without leaving permanent signs in the shape of cicatrices. The question has often been mooted as to whether the two are not identical in origin and only different in degree. It is, of course, of some importance to be able to distinguish between the true conjunctival diphtheria and fibrinous inflammations, in the causation of which Loeffler's micro-organisms play no part. Our author's patient was a sickly child, fifteen months of age, who came under observation four days after the swelling began. There was, when first seen, a moderate swelling with redness of the lids, which were nevertheless ductile and easily everted. The upper palpebral conjunctiva on each side was covered by a gray false membrane, moderately thick, adherent to, but easily separated from the mucous membrane; the removal of this layer exposed a raspberry-like bleeding surface; both cornea were infiltrated, especially in the central part. No membrane could be discovered in the fauces; a few large mucous râles could be heard in the chest. The treatment consisted of a sublimated lotion (1 to 2000), iodoform ointment and atropine.

Improvement soon took place; July 6th the membrane had disappeared. Ulceration of the right cornea occurred and hypopyon formed, but after paracentesis the ulcer healed.

In the tubes of gelatine inoculated from the membrane, and kept at a temperature of 37° C., colonies were visible on the second day. These were of two varieties; one opaque and white, and the other grayish. One variety proved to be the streptococcus pyogenes; and the other the staphylococcus pyogenes albus; no species of bacillus was found in any of the cultures.

Fage considers that these results establish the non-diphtheritic nature of his case, and is of the opinion that a correct diagnosis can only be ascertained in the presence or absence of the bacillus of Loeffler, which is generally considered a characteristic of diphtheria.

<sup>6</sup> *Arch. Ophthalmol.*, January and February, 1891.

#### A FORM OF XEROSIS.

Kollock<sup>6</sup> reports a rather peculiar form of this disease as prevalent among negro children in Charleston, S. C.

The conjunctiva has a dirty-white and yellowish-green hue, and that portion of the conjunctiva visible between the lids is darker than the rest, and generally thicker near the corneal margin.

The pigment is distributed well back into the retro-tarsal folds, but does not invade the palpebral conjunctiva. The ocular conjunctiva may be merely thickened and discolored, or it may be relaxed and flabby so that every movement of the ball throws it into folds or wrinkles about the cornea. Occasionally these folds are capped by the silvery scales which some writers have described as being diagnostic of hemeralopia, and indeed the parents of a few of the children have mentioned night blindness as the sole cause of bringing them for treatment. The edges of the cornea are always hazy and sometimes an ulcerating ring surrounds that body which has a bluish hazy sheen, due to a partially opaque state of the epithelium. The eye is not painful, nor is there any photophobia.

#### APPARENT DIFFERENCES OF DISTANCE DUE TO COLOR.

Basevi<sup>7</sup> has made the peculiar discovery that when different colors are placed upon the same black background in the same plane, they appear to be at different distances from the eye. At the distance of five metres, yellow seemed to be about one and a half centimetres and red about nine-tenths of a centimetre nearer than the blue on the colored background. These apparent differences changed, but according to certain definite laws.

#### BRAIN CENTRES GOVERNING THE IRIS.

Basevi<sup>8</sup> has made numerous experiments on dogs, cats, rabbits and pigeons to fix the seat of the centres governing the movements of the iris. According to the results of his observations, the centre for the sphincter lies in the posterior wall of the third ventricle in front of the corpora quadrigemina, and in the medulla oblongata; and secondary centre lies in the ciliary ganglion. The centre governing the dilatation of the pupil is found between the lower part of the last cervical vertebra and the first two dorsal vertebrae, and in the posterior part of the anterior pair of the corpora quadrigemina, and at the posterior pair. A second centre lies in Casser's ganglion. Our author found no difference between mammals and birds in regard to these centres.

#### CAUSE OF THE LIGHT STREAKS AS SEEN UPON THE CENTRE OF THE RETINAL VESSELS.

Davis<sup>9</sup> has repeated Loring's experiment by passing through a glass cylinder a column of fluid from a warm-blooded animal, making the analogy between the artificial eye constructed by Loring and that of the human eye complete, and has gotten in every detail the same phenomena with the actual warm-blood column that Loring did with the canine solution, thus disarming the criticism of Donder's, and establishing the fact that the light streak as seen upon the

<sup>6</sup> *American Ophthalmological Society*, 1890.

<sup>7</sup> *Arch. Ophthalmol.*, vol. 8, 4, p. 330.

<sup>8</sup> *Annals of Ophthalmol.*, vol. XIX, 2, p. 111.

<sup>9</sup> *Archives of Ophthalmology*, vol. XX, 1, p. 14.

centre of the retinal vessels was due to the refraction of the reflected light.

#### RESECTION OF THE OPTIC NERVE.

Sheffels<sup>10</sup> reports forty-one cases of resection of the optic nerve by Dr. Pagenstecher. Dr. Sheffels was resident surgeon of the Eye Hospital at Wiesbaden. Pagenstecher adopted this operation on account of the troubles which attend the wearing of the best-made artificial eye, especially among the poorer class of patients, and on account of the moral effect of the operation, and also from the fact that an enucleation militates against the man in the labor market.

The simple operation of neurotomy which was practised for a time by the late Alexander Pagenstecher, was abandoned later on account of the reunion of the divided nerve ends, and replaced by resection. The first cases tried in this manner were those in which the lost eye was painful, and the success which followed led to its employment in those cases in which there was reason to fear that the lost eye might lead to sympathetic inflammation in the second eye. In 15 cases the blind eye was the direct cause of suffering, — secondary glaucoma, irido-choroiditis, detachment of the retina, cyclitis, etc. In seven of these 15 cases it was the cause of sympathetic irritation of the sound eye, and this disappeared after the operation.

In 26 further cases, sympathetic inflammation of the other eye was feared, either in a shrunken globe after perforation, or recent injuries involving the ciliary body, cornea, or iris; by percussion caps, iron, stone, etc. Total anaesthesia of the cornea was always present immediately after the operation, but was not permanent. The margin of the cornea, at first, and the remainder after a longer period, generally recovered a subnormal degree of sensibility. The pupil, in the absence of synechie, generally acquired a maximum dilatation. The longest piece of nerve removed measured 15.5 millimetres. It was not possible often to remove so much in the presence of inflammatory adhesions around the globe. A simple optico-ciliary neurotomy is not a sure preventive of sympathetic inflammation, and the author reports a case from Pagenstecher's practice in addition to the one reported some time since by Leber.

From the results obtained, the author draws the following conclusions:

In all cases in which the blind eye is the sole cause of suffering, or in which the sympathetic irritation of the fellow-eye exists, but when sympathetic inflammation is not to be feared, resection of the nerve is preferable to enucleation.

In all cases in which sympathetic inflammation is to be feared, it is now desirable that resection should be freely tried as a substitute for enucleation, in order that its efficacy may be definitely determined; and, should sympathetic ophthalmia occur in a single instance after the removal of a sufficient portion of the nerve, at an early period, as has twice happened after a simple neurotomy, then for this class of cases the operation must be abandoned.

#### SHADOW-TEST IN THE DIAGNOSIS OF AMETROPIA.

Beaumont,<sup>11</sup> in a monograph of thirty-eight pages, an author who has evidently paid great attention to the subject, gives an account of the practical use of

the shadow-test, which term he prefers to retinoscopy, and wisely warns his readers of the danger of using the shadow-test to the exclusion of other more important methods of examination, and also emphasizes the necessity of ascertaining the refraction at the macula, and not at other portions of the fundus oculi; and gives some tables of figures as to the differences in refraction at the yellow spot and at the periphery.

In regard to the use of mydriatics in cases in which the shadow-test is to be used, the author differs from most authorities in that he considers it more essential to paralyze the accommodation in myopes than in hypermetropes, but there is some reason for this opinion, inasmuch as there is danger of over-correction in myopia, whereas in hypermetropia the error, if there be one, will be one of under-correction.

#### PERSISTENT HYALOID ARTERY.

De Beck<sup>12</sup> in a rather elaborate compilation of all recorded cases, groups persistent hyaloid arteries under the following heads:

Group A, in which are found upon the optic disc little irregular shreds or bands of connective tissue. These are glistening white, at times almost transparent, only faintly softening the vessels that may run beneath them; and again, are thicker and more opaque, either completely hiding the vessels beneath, or allowing them to shimmer faintly through. In a strict sense, these are not obliterated vessels, but are remnants of an obliterated vessel, the hyaloid.

Group B. A small series of cases have been reported in which a glistening white membrane was found covering the disc to a greater or less extent, and in most cases encroaching somewhat upon the adjoining retina. This membrane usually presents considerable thickness, and either completely hides the vessels, or obscures them to a more or less degree. Our author thinks these membranes are remains of the adventitia of the embryonic hyaloid vessel.

Group C. Also a small group of cases where the remnant of a hyaloid vessel was found occurring as a cystic expansion upon the disc. These show rounded or oval. They have a characteristic translucent tint, and are very suggestive of fluid contents, and are pearly gray or steel, bluish in color.

Group D. Quite a group of cases have been reported where the disc is more or less covered and hid by the irregular mass of connective tissue. This group presents the greatest variability, and forms the most general connecting link between the other groups, varying from bands and membranes to other cases in which it affiliates with the group of cystic remains, and may project forward considerably into the vitreous.

Group E is the largest group of all, and is characterized by a strand arising from the disc and passing downward for a greater or less distance, and terminating by an end which floats free in the vitreous. Usually the origin of the strand can be traced clearly to the central artery, although some take the origin from a branch upon the disc. The length is, of course, variable; they may sub-divide into two or three branches, and may terminate either in kind of knob-like swellings, or in fine fibrillae.

Their color varies from grayish, bluish, brownish to black — to some extent modified by the method of illumination.

Group F is a small one which resembles the pre-

<sup>10</sup> Klin. Monatsbl. f. Augenheilkunde, June, 1890, p. 197.

<sup>11</sup> Ophthalmic Review, London, August, 1890.

<sup>12</sup> American Ophthalmological Monographs.

vious one in having a strand springing forward from the disc, and ending free in the vitreous, but differs in presenting in addition a distinct remnant at the posterior pole of the lens, indicating the former attachment of the artery at this point. This attachment is not always central.

In Group G the hyaloid remnant retains its attachment at its point of origin upon the disc, as well as its distal attachment at or near the posterior pole of the lens.

Group I includes a few cases in which the only vestige of the hyaloid artery is a filament attached to the posterior pole of the lens, projecting back and ending free and movable in the vitreous; the fundus is normal, and the vitreous clear.

The last group is one in which there remains as a vestige of the hyaloid system, a delicate, nearly transparent tubular sheath, passing through the centre of the vitreous from the disc to the lens. This is regarded by some as a persistence of the delicate membranous lining of the canal of Cloquet, through which the hyaloid artery runs, and by others, as the remains of the outer sheath of the vessel itself. Sometimes the sheath fades away towards the disc, and only a thin, pointed extremity fixes it at this point; and even this may fade away, so as not to be visible to the ophthalmoscope. Anteriorly the sheath may fade away in the same manner, and not reach the posterior surface of the lens. There is little doubt but that in some instances, at least, this canal remains patent during life.

Galezowski notes a case where a very fair example of the persistence of the posterior portion of this canal had been observed in an infant; three years later this had dwindled to a few shreds floating at the disc. From this he concludes that this condition is quite frequent in infancy. This conclusion is hardly warranted, however, from a single observation.

#### THE CONJUGATE MOVEMENTS OF SQUINTING EYES.

Brown,<sup>10</sup> in a short article, draws attention to the fact, that, under ordinary circumstances, the centre for conjugate movements acts in the same manner in squinting eyes as in those with parallel axis; but, that when once the limit of internal has been reached by one eye, the external rectus of the fellow eye is able to exert an independent and supplementary action. This action continues only so long as the habitual angle of the visual axis is exceeded. When it is re-established, conjugate movement is re-established also. Beyond this, it indicates that the internal rectus is capable of being elongated by the power of the external, and that there is no actual shortening of the muscle as supposed by some. This is demonstrated in the following:

Supposing the left is the squinting eye; let the patient fix an object, such as a pencil, held in the mesial line. Let this be moved to the temporal side till the extreme lateral excursion of the fixing eye is attained; the left eye wick, of course, he now turned towards the nasal cantus; if now the object of fixation be slowly moved from the right to the left side of the patient, it will be found that the fixing eye (right) travels as far as the mesial line before the left begins to move in concert, that is to say, the fixing eye moves, but the squinting eye remains stationary.

When the right eye has reached the mesial line, then both eyes move in due association towards the left.

### BOSTON MEDICO-PSYCHOLOGICAL SOCIETY.

H. C. BALDWIN, M.D., SECRETARY.

MEETING of March 19, 1891.

DR. EDWARD B. LANE read a paper on

#### HALLUCINATIONS IN THE INSANE.<sup>1</sup>

DR. TUTTLE had no doubt that a person could educate himself to hallucinations and illusions, and cited the case of a woman who lost her child, and went to mediums in order to communicate with the child. She then began to try to communicate with the child by herself. She would go off alone, and lie quiet for hours, listening, until she finally developed hallucinations of hearing. She is now in an asylum with persistent false hearing. He said that if these patients' attention can be taken up, the hallucinations of hearing stop. Change of environment and occupation offered the best chance of recovery in these cases.

DR. PRINCE thought that most of the mediums were developed in the way Dr. Tuttle suggested. They educate themselves to see visions and to have trances. When going to sleep but while yet awake, one can often see faces and things distinctly and apparently objectively. Regarding patients with hallucinations of digestion, he spoke of an insane patient with a series of neurotic symptoms connected with digestion, where there really was no digestive trouble. This was the result of the grouping of a lot of nerve centres (association neurosis) from past true digestive attacks.

DR. DEWEY spoke of a patient with folie circulaire who was seven times in the South Boston Hospital. In six previous attacks the patient had no hallucinations. In his last attack the patient had hallucinations of sight and hearing.

DR. KNAPP thought this was an instructive study, and was surprised to find that hallucinations were so universal in cases of different forms of insanity. The greater prevalence of hallucinations of hearing was most interesting, and as the writer said, was explained by the fact that visual was later than auditory representation. Dr. Tuttle's remarks emphasize the importance of studying the earliest manifestations of hallucinations which may begin in health.

DR. MOULTON spoke of a case where hallucinations of hearing had persisted for ten years. The patient recovered by means of diversion and occupation.

DR. STEEDMAN said that it was unusual to have hallucinations in cases of folie du doute.

DR. FISHER spoke of the difficulty of deciding about hallucinations in the case of criminals whom one sees but a few times. The existence of hallucinations would be very important in the evidence. He spoke of a patient with monomania of suspicion who had Ménière's disease and who had false hearing. The false hearing associated with Ménière's disease was interesting and unusual, and suggested the question whether the disease was the cause of the mental state. Later authorities state that vertigo may be central with no disease of the semicircular canals. In one of his patients where there were vertigo and forced movements, the autopsy showed no Ménière's disease.

DR. GORRAN spoke of the case of a man who could not work so well as usual in consequence of overwork, but recovered after resting. He broke down a second

<sup>1</sup> See page 267 of the Journal.

time, and became convinced that other people felt about his work as he felt himself. This was not the case. Six months later he developed the feeling that people were talking about him. When he saw two people together for whom he worked, he heard them talking about him. The voices faded when they went away. Later, when other people came together and talked, he also heard them talking about him. At first the talk was logical; later it became childish and silly. Ultimately the patient developed hallucinations and delusions which were classical in character.

DR. TUTTLE said that when a man heard words, he thought that usually there was some sound, and he had come to look upon these auditory hallucinations as usually associated with sound. He cited the case of a patient whose footsteps talked to him. When the attendant walked, his footsteps talked also. The patient did not mind the talking of his own footsteps, but did mind the talking of the attendant's footsteps.

#### NEW YORK STATE MEDICAL ASSOCIATION. FIFTH DISTRICT BRANCH.

SEVENTH annual meeting, held in Brooklyn, May 26, 1891, the President, STEPHEN SMITH, M.D., in the chair.

##### MORNING SESSION.

After the disposal of some preliminary business matters and the reading of biographical sketches of Fellows deceased during the year, DR. SAMUEL E. MILLIKEN read a paper on

#### THE TREATMENT OF HYDROCELE BY CARBOLIC INJECTION VERSUS THE RADICAL OPERATION.

The cutting operation of Volkman, and its various modifications, he said, while usually successful in relieving the hydrocele, requires the use of an anæsthetic, and necessitates confinement to bed for a week or more if suppuration occurred. The method of Levis, by carbolic injection was practically painless, confinement to bed was in no sense essential, and unless an inordinate amount of carbolic acid, more than thirty minims was used, sloughing ought never to occur. The simplest and most efficient apparatus for the purpose was a small trocar and a hypodermic syringe. After thorough evacuation, the syringe was screwed on to the canula, and the injection could thus be made without a single drop of the acid coming in contact with the skin of the scrotum. When from five to 25 minims of pure carbolic acid was distributed over the whole serous surface (two or three minims in each place) nothing more than a sense of warmth was experienced by the patient. After removal of the canula slight kneading of the sac might be made to insure coating of its walls with the irritant.

Of 54 cases thus treated by Dr. Milliken at the Hospital for Ruptured and Crippled, nine were never seen after the injection, five paid one visit within the first week only, and four are at present under observation. All the remaining 36 cases could be set down as completely cured; and of these, 27 had one injection, four, two injections, and five, three injections. In no case had sloughing occurred, and not one of the patients lost more than 24 hours from business. From two to six weeks were necessary for absorption of the exudation to take place, and thickening of the sac

might remain much longer than this. The conclusions reached by the author were as follows:

(1) Carbolic injection is a safe method for the cure of hydrocele.

(2) It is practically painless.

(3) The patient can attend to business without more than one day's delay.

(4) The disagreeable effects of an anæsthetic are avoided.

DR. WM. R. BALLOU said that Hare had collected a large number of cases in which great destruction of the tissues, and one case in which fatal poisoning, was caused by the injection of iodine, and he thought carbolic acid was greatly preferable to the latter. Dr. Fluhrer was accustomed at the New York Polyclinic to inject a large quantity of carbolic acid (from 60 to 80 minims), but it would seem hardly necessary to use such a large amount when such excellent results as those reported by Dr. Milliken could be obtained with small injections.

DR. WM. T. WHITE said that while he had never seen any of the bad results from iodine which had been mentioned, it was a fact that in cases where considerable inflammation was set up by the latter, it was necessary for the patient to remain in bed for two or three days, and, therefore, if this could be avoided by the use of carbolic acid it was certainly a point gained.

DR. MILLIKEN said that in regard to iodine he was not so much in fear of the sloughing liable to be caused by it, as of iodine poisoning. The painlessness of carbolic acid he thought was a great point in its favor. In the paper, he said, he had omitted to state that he usually directed a suspensory bandage to be worn for the first two weeks, and that he employed for the injection equal parts of glycerine and carbolic acid, a perfect solution being highly desirable. He preferred to use 10 to 20 minims, and repeat the injection a second, or even a third time, if necessary, rather than to use a large quantity of the acid a single time. In cases where the trouble returned it was always noticeable that the hydrocele was never as large as it had been originally.

DR. WM. R. BALLOU read a paper on

#### ACUTE PROSTATITIS AND PROSTATIC ABSCESS.

In one thousand cases of urethritis in various stages seen in hospital and dispensary practice during the past five years, he said he had observed only three cases of prostatitis resulting in an abscess of the gland, though many of a milder grade. In the more severe form of the affection the termination might be either in resolution or in prostatic abscess. Many distinct foci of suppuration were sometimes present, and perforation and discharge might be either into the urethra, the rectum or the perineum. The most frequent cause was extension of inflammation from the anterior urethra; and among the other causes were cold, traumatism (including the use of instruments), and irritating urethral injections.

Having described the symptoms in the milder form, he said that in the severer form the temperature might rise to 101° or 105°. Swelling, pain and throbbing in the rectum were marked, and defecation might be painful or much interfered with. As the formation of pus came on, all the symptoms became intensified, and even general movements of the body were accompanied by agonizing pain. There was also a sudden accession of fever, usually with rigor and sweating. More or less

complete retention of urine might be present; but prostatic fistula or extravasation of urine were rare, owing to the fact that the surrounding tissues were very tense from cellular infiltration. Having spoken of the prognosis, he said that in the beginning of the attack all local urethral medication was to be stopped and absolute rest in bed enforced, if possible. A brisk purge has advisable at first, and later on laxatives were to be given at intervals. Such alkalies as citrate of potassium (ten grains) or liquor potassæ (five drops), given every three hours with tincture of hyoscyamus (two drachms), he had found most efficacious in diminishing the pain and frequency of micturition; and he advised that they should be kept up during the whole course of the disease.

Local remedies to the perineum, such as leeches, hot fomentations, fly blisters and cantharidal collodion, as well as hot hip-baths, were often of service. Morphia internally or suppositories of opium and belladonna were sometimes required by the intense pain present. If retention of urine occurred, a soft catheter should be passed after irrigating the urethra with a mild solution of permanganate of potassium. Incidentally, Dr. Ballou said that in ordinary acute urethritis he had obtained more prompt and satisfactory results with permanganate injections than with almost any other, and that he now used this treatment almost exclusively. After drawing off the water, the bladder should also be washed out. In some cases of retention a metallic instrument might be required; but it should be used with extreme caution, and aspiration above the pubes was sometimes preferable.

If abscess formed, free incision was called for, and even if fluctuation was not distinct, a free and deep perineal or rectal incision was afterward followed by the most beneficial results. After evacuation, under antiseptic precautions, the abscess should be washed out with bichloride solution, and a large drainage-tube inserted. Passage of a sound into the bladder, in the hope of rupturing the abscess into the urethra had been sometimes recommended.

In conclusion, Dr. Ballou gave the notes of three cases of acute prostatic abscess treated by him. In one the abscess had discharged spontaneously into the rectum before the patient came under observation; in another it was tapped with a trocar through the rectum; and in the third an incision was made from the rectum (after the introduction of a Sims rectal speculum).

The President said that in the earlier stages he thought it preferable to make the perineal rather than the rectal incision, on account of the danger with the latter of the opening remaining permanently and also of infiltration of the tissues. If the case were seen later, and the abscess was evidently pointing towards the rectum, he would perform rectal incision. He regarded the passage of a metallic instrument into the bladder with the idea of causing rupture into the urethra as a dangerous and unjustifiable procedure, and referred to a case where this was done, which terminated fatally in consequence.

#### THE TREATMENT OF GONORRHEA.

In reply to a question, Dr. Ballou stated that he was in the habit of using in acute urethritis six hourly injections of the strength of one-eighth to one-tenth of a grain of permanganate of potassium to the ounce of distilled water; two syringefuls being employed at each injection. Internally he usually gave some alkalies,

and if the trouble were deep seated, hyoscyamus in addition. After from four to eight days sulphate or acetate of zinc (one grain to the ounce), was added to the injection.

Dr. WM. McCOLLOM said that it might be objected to such a weak permanganate solution that it was scarcely germicidal. He himself had generally used the permanganate in the strength of one grain, or, all events, half a grain, to the ounce.

Dr. BALLOU thought that the gonococcus at the present time was not regarded as of quite as much importance as formerly. While he used the very weak permanganate solution in the first stage, he often increased the strength to one-sixth of a grain to the ounce afterwards; but this was as strong as he ever employed it.

Dr. PRITCHARD said that he had formerly used the permanganate, but he found that while with this injection, as with many others, the discharge disappeared for a time, it almost always came back again.

(To be continued.)

### Recent Literature.

*The Vest-Pocket Anatomist.* By C. H. LEONARD, A.M., M.D. Fourteenth Revised Edition. Containing Dissection Hints and Visceral Anatomy. Detroit: The Illustrated Medical Journal Co.

It is the boast of the reviewer, repeated yearly, and as often made good, that he can "pluck" any student who trusts to compendiums. The book before us does not call for further notice. T. D.

*Auscultation and Percussion.* By FREDERICK C. SHATTUCK, M.D. Professor of Clinical Medicine in Harvard University; Visiting Physician, Massachusetts General Hospital, etc.

This little book of 120 pages is very concise and remarkably well written. Seven plates of outlines at the beginning of the book add much to its value. The first fifty-six pages are devoted to the lungs. Among its many excellences we notice with pleasure what is said about palpation in the first chapter. The views expressed in the page devoted to the merits of gentle percussion will also meet the approbation of the modern teacher. Much of the rest of the book is devoted to the heart and aorta, while the last chapter deals with the physical exploration of the liver, spleen and pancreas. In conclusion, we may add that the different subjects are handled with great clearness and discrimination, and that the book more nearly attains the ideal of a compendium than any we have. It is to be unhesitatingly recommended to physicians and students alike as the best of its kind.

APPOINTMENTS IN FOREIGN UNIVERSITIES.—Professor Schanta, of the University of Prague, has been appointed to the Chair of Midwifery, with charge of the First Obstetrical and Gynecological Clinic, in the University of Vienna, in place of the late Prof. Carl Braun. Professor Löffler, of Griefswald, has been invited to succeed Professor Rubner in the Chair of Hygiene in the University of Marburg. Professor Rubner has gone to Berlin to take the position formerly held by Professor Koch.

**ON THE ROLE OF ALCOHOLISM IN THE ETIOLOGY OF GENERAL PARALYSIS.**

At the Congress of Mental Medicine held in Lyons, August 3, 1891, the subject which elicited the most discussion was that of the rôle of alcoholism in the etiology of general paralysis.

Rousset, who opened the discussion by an exhaustive report, concluded that predisposition is equally as important a pathogenic factor as alcoholism; there are, however, exceptional cases where, apart from any hereditary influence, alcoholic excesses may determine at length those processes of connective tissue proliferation and cerebral sclerosis, which find expression in paralytic dementia.

Magnan defended the view propounded in his well-known work, namely, that chronic alcoholism leads habitually to dementia and sometimes to general paralysis; this view being supported by arguments borrowed from experimental physiology on the one part, and from clinical observation and pathological anatomy on the other.

Experiments on animals subjected to chronic alcohol poisoning, give as results thereof, steatosis of the liver and kidneys, sclerosis of the pericardium, of the meninges, and of the posterior columns of the cord. In man, similar lesions are noted as the effect of prolonged alcoholic excesses; the morbid process localizes itself in accordance with individual predisposition, and when it affects the cerebrum, it determines the symptoms of dementia.

Regis stated that he had formed his opinion from data obtained in the private asylum of Castel d'Andorte. He finds that in the middle classes of Gironde cases of general paralysis and of alcoholism are in absolutely inverse proportion, and that in this region, at least, alcoholism has no influence on the production of general paralysis. On the other hand, almost all cases of general paralysis are old syphilitic patients; and this leads him to assign an important rôle to syphilis as an etiological factor in general paralysis.

Maricé, of Paris, regards ordinary toxicological

agents (mercury, lead, opium) as factors of no account in general paralysis. Nor do the infectious poisons (those of acute diseases) seem to have any influence in the genesis of this disease. Syphilis, on the contrary, as a chronic infectious process, has been found to be pathogenic in sixty-five per cent. Alcoholism and syphilis combined, associated with heredity, seem to form a sort of triad with predominant etiological influence. So impressed is this authority with the importance of heredity, that he regards general paralysis rather as a degenerative affection of the race than of the individual.

Combemale, of Lille, stated that he had induced in dogs the characteristic symptoms and lesions of general paralysis by dosing them with daily quantities of alcohol, introduced by the stomach tube; these experiments were made in conjunction with Mairret. These are his conclusions:

(1) Chronic poisoning by alcohol gives rise in the dog to outbreaks of delirium characterized especially by ideas of fear with hallucinations.

(2) To these symptoms which generally mark the onset of the psychical troubles, are shortly added mental enfeeblement and muscular disorders, both ataxic and paralytic, which begin by the posterior extremities or at least have their maximum there, and rapidly become general, as in general paralysis.

(3) At the autopsy of the animals are found the principal lesions which characterize general paralysis; diffuse-meningo-encephalic inflammation and vascular dilatation.

(4) To the nervous disorders of the limbs are to be added certain choreiform tremblings of the head and neck, and modifications of character and of instinct; thus an animal of snappish, churlish disposition would become mild-mannered and tolerant of excitation.

These physical and mental disturbances were thought to justify the diagnosis of general paralysis of special form.

Christian thought that it would not do to give to the morbid accidents noted in the dog by Combemale the name of general paralysis. They simply show that alcohol causes in the dog delirium and paralysis. With this opinion Mairret coincided. He believes that alcohol may determine in man the appearance of a special form of general paralysis, quite distinct clinically and anatomically, from ordinary general paralysis.

Magnan did not dispute that alcoholism gives to general paralysis a special physiognomy, which results from the distribution of the lesions. But this is no reason for creating a special form of general paralysis.

Charpentier affirmed that hospital statistics have proved that it is in alcoholic patients that general progressive paralysis acquires its maximum of frequency. In the last five years he has found at Bicêtre, eighty-three cases of confirmed alcoholism out of one hundred and thirty-five victims of general paralysis. If general paralysis of alcoholic origin takes on a special form, this is due to the nature of the intoxicant, its

affinities for particular tissues, and the kind of irritation it provokes.

From an anatomico-pathological point of view, alcohol-poisoning may produce the entire symptomatic complex known as progressive general paralysis, and at the autopsy one may fail to find the characteristic lesion of general paralysis, that is, diffuse interstitial sclerosis. *Per contra*, there is no diffuse interstitial sclerosis without general paralysis, while there may be general paralysis without this anatomical lesion.

From the foregoing discussion, it will be seen that pathologists have not yet, with sufficient precision, defined the pathological anatomy, the symptoms and the course of that morbid entity designated under the name of general paralysis, and till this is done, as was remarked by one of the speakers at the meeting, the question of the rôle of alcoholism in the etiology of general paralysis cannot be satisfactorily answered.

#### PERMANENT PUBLIC BATHS FOR THE POOR.

In the latter part of August there were opened, with simple ceremonies, the first permanent public baths in the city of New York. The building is situated on Centre-Market Place, in the midst of the east-side tenement district, about half-way between Broadway and the Bowery, and it has been erected at a cost of about \$25,000 exclusive of the land, which was kindly given for the purpose by the New York City Mission Society. The project has been carried out by the Association for Improving the Condition of the Poor; and on the occasion of the opening of the baths an address was made by Mr. John Paton, President of the Association, and a poem read by Dr. Gouverneur M. Smith, one of the principal movers in the work. The building is attractive in appearance, and its accommodations are capable of providing nearly one thousand baths a day. The departments for the two sexes are entirely distinct, with separate entrances, so that males and females can bathe at the same time, and the baths are to be kept open for fifteen hours a day, winter and summer.

The system adopted is that which has been in use for some time in Vienna and other European cities, namely, the shower or rain-bath plan. Adjoining each compartment is a small dressing-room, and most of the baths are furnished with warm as well as cold water. Each bather is provided with a towel of ample size and a small cake of soap, and he is expected to carry home the latter. The price for a bath is five cents, but provisions have been made by which the very needy can secure their baths for nothing. One hundred and twenty-five people are reported to have availed themselves of the baths the first morning they were opened. These new "People's Baths" are the direct result of a movement commenced some time ago by the medical profession, and the Association for improving the Condition of the Poor is to be congratulated on having carried it out to so happy a consummation.

#### STATE CARE OF EPILEPTICS.

THE Department of Health of the American Social Science Association occupied itself at the meeting at Saratoga last week with a consideration of epilepsy, insanity, hypnotism and hydrophobia.

Dr. F. Peterson, of New York, chairman of the department, was not present, but contributed a paper on "State Care of Epileptics." This subject was discussed in a paper by Dr. W. N. Bullard, published in the *JOURNAL*, January 8, 1891, and at a meeting of the Clinical Section of the Suffolk District Medical Society, reported in the same issue. Dr. Peterson agrees with the views then advanced as to the need of special institutions—he suggests one in each State—for the care of epileptics. He estimates that there are more than 100,000 epileptics in the United States, and that there are at least 2,000 in the almshouses and asylums of the State of New York. He hopes New York will follow the example already set by Massachusetts, Ohio and California in making separate provision for these unfortunates.

#### MEDICAL NOTES.

**CASE OF LUPUS UNDER TREATMENT WITH TUBERCULIN SINCE FEBRUARY.**—The medical officer in command at Cincinnati, under date of August 20th, reports as follows to the Surgeon-General of the Marine-Hospital Service: "I have the honor to inform you that the use of tuberculin has been discontinued in the case of lupus of seventeen years' standing, transferred from Washington, D. C., to this station, for a continuation of treatment with tuberculin, commenced by Assistant Surgeon Geddings, February 11, 1891. The destruction of tissue by advancing ulceration and sloughing was more marked in the last fortnight of treatment than at any time during the entire period of the existence of the disease. In view of the condition of the lupus patch, it was deemed advisable to abandon the use of tuberculin."

**THE CENSUS OF CANADA.**—Canadians are much disappointed over the result of the census. The enumeration gives the Dominion 4,823,344 inhabitants, an increase of 498,531 in the decade, or rather more than eleven per cent. Most of the gain was made in the Western provinces, in Ontario, in Manitoba, and in the newly developed country along the Pacific coast. Thus Toronto, which had 96,196 inhabitants in 1881, now is credited with 181,220; Winnipeg has grown from 7,985 to 25,642; Victoria, British Columbia, from 5,925 to 16,841, while Vancouver, which was only a city on paper in 1881, now has 13,685 inhabitants. Hamilton, Ottawa, London and Kingston all report large gains, and are now considerable cities, Hamilton leading with 48,980, closely followed by Ottawa with 41,151. In the Province of Quebec the greatest gain is made by Montreal, which has a population of 216,650, against 155,237 in 1881. Quebec has 63,090 inhabitants against 62,446 in 1881. In the Maritime Provinces the loss of population is most

marked, St. John's population has declined from 41,353 to 39,179. Eight of the nineteen electoral districts in Nova Scotia have lost population. The same return is made for eight of the fifteen New Brunswick districts. There are three districts in Prince Edward Island, one of which is returned with the minus sign. Halifax has gained 2,456 inhabitants, having now 38,556.

## BOSTON.

JAMES J. MINOT, M.D., of Boston, has been nominated by Gov. Russell, trustee of the Massachusetts Hospital for Dipsonanics.

**LEGISLATIVE REGULATION OF EMBALMING.**—At the tenth annual meeting of the New England Undertakers Association held in Boston, September 2d, Medical Examiner Thomas M. Durell, of Somerville, addressed those present in regard to the bill presented last year to the Legislature for the regulation of embalming. He recommended co-operation between medical examiners and undertakers. He thought that a law could be framed that would be for the interest of both and the public as well. He suggested the appointment of a committee of five to meet a similar one from the medico-legal society, and to draft a bill for presentation to the Legislature, and see that the measure passed. His proposition was adopted. Mr. A. E. Mann, the Association's secretary, spoke of the personal work done by the Massachusetts undertakers against the passage of the anti-embalming bill, and advocated the formation of a State association, in addition to that which includes the six New England States.

Mr. C. B. Dolge, of Westport, Ct., read a paper on "Embalming as a Fine Art." He said, "There is no question which demands so much attention from undertakers as the art of embalming. Through your Association we have been able to call the attention of doctors, lawyers, legislators and the public to ourselves and you will derive great benefit from it. Embalming is an art which is most difficult of mastery—not so easy as the manufacturers of some new fluid which they desire to sell would have you to believe. There are about 14,000 undertakers in the States, of which number only about half do more or less embalming. This is a small showing, and, because so many have but a superficial knowledge of the art and frequently fail, all good embalmers suffer." He spoke of the work of the United States College of Embalming, with which he was connected. It teaches all that is deemed necessary for a clear understanding of the human body and its anatomy as far as is needed to do the work intelligently and correctly. The study of chemistry was not considered necessary, as there were plenty of standard fluids, manufactured by responsible firms that could not afford to put an inferior fluid on the market. A good embalmer readily discovers which fluid is the better. He particularly emphasized the necessity of careful instruction in embalming.

The president, after this essay, announced the following committee on legislation: Messrs. Lawrence

Reed, A. E. Mann, George Waterman, George N. Hopkins and Oliver Walton. It was then decided to have a committee of one from each State to look after legislative matters, and President Foster appointed as this committee: E. A. Brophy, of Maine, H. B. Knowles, of Rhode Island, E. D. Ward, of New Hampshire, C. W. Hills, of Connecticut and L. E. Cabot, of Vermont.

## NEW YORK.

**THE DEATH-RATE.**—The report of Dr. Nagle, Deputy Registrar of Records of Vital Statistics, for the week ending August 29th, shows a slight increase in the death-rate. The number of deaths was 826, representing an annual death-rate of 25.52 per thousand of the population against 773 and 23.89 the week previous, and 791 and 24.43, the average for the corresponding period during the past five years. The deaths from violence, however, which have averaged 32 per week since 1885, were increased to 107 by the Park Place disaster; and but for this the mortality of the city would have been under the average. There is some reason to suppose that an increase in the number of cases of typhoid fever reported may be due to the contaminated condition of the Croton water-supply.

**POLLUTION OF THE WATER-SUPPLY.**—The Board of Health is at present engaged in a careful examination of the existing sources of pollution along the Croton water-shed, and at its last weekly meeting adopted a resolution calling upon the State Board of Health to report to the New York City Board of Health the names and residences of all persons now ill with a communicable disease, and those who may hereafter become ill of such disease, who reside on the Croton water-shed; also to report at once all deaths occurring on the Croton water-shed, with the name of the disease and the residence of the deceased.

**INSUFFICIENT ACCOMMODATION FOR THE INSANE.**—The overcrowded condition of the Brooklyn public insane asylum at Flatbush, where 1,400 patients are forced to occupy quarters intended for 900 at the most, and where even the damp cellars have to be used to lodge the unfortunate inmates, was the subject of an official complaint by the Charities' Commissioners to the Kings County Board of Supervisors on August 27th. Their statement showed that the main reason for this condition of affairs was the failure to complete the structures in course of erection at the county farm at St. Johnland.

## Miscellany.

## THE PHYSIOLOGICAL ACTION OF KOLA-NUT.

DR. KOTLIAR,<sup>1</sup> wishing to elucidate the action of kola-nut, which, as is well known, has been recommended for increasing the power of the body to undergo a severe strain of work, has made a series of observations in Professor Manassein's clinic in St. Peters-

<sup>1</sup> Wratsch, No. 19, 1891.

burg, on the alteration of the chemical processes of the body when under the action of the drug. The observations were made on seven healthy young men, each being observed for two consecutive periods of five days. In some the drug was given during the first period, and the subject was kept at rest from work. In others the subjects worked hard, and the drug was given during the second period. The quantity of powdered kola-nut taken per diem was a drachm. From careful analysis of the food and excreta, it was found that, under conditions both of rest and work, kola increased the assimilation of phosphorus and sulphur. That of chlorine was increased during rest, but was not altered by kola under conditions of work. The metamorphosis of chlorine was diminished by kola both under conditions of rest and work, especially in the latter case. The metamorphosis of phosphorus was diminished both at rest and at work, but more especially during rest. The same may be said of sulphur. Finally, the breaking up of phosphorus and sulphur compounds both during rest and work, as compared with that of nitrogenous compounds, was diminished.

#### MISTAKES ABOUT BEARINGS.<sup>1</sup>

MISTAKES in orientation—sometimes of the most puzzling character—are usually the result of some incidental and temporary bewilderment, and may under peculiar circumstances overtake any one. Some instances have been cited by Sir Charles Warren in which they are chronic and may afflict even the best-informed persons. Erroneous conceptions formed by children as to distances and positions may grow up with them undetected till near maturity. Then, when the discovery is made, it is too late to apply any better remedy than to recognize the error and make allowance for it when possible. Cases are cited of a person whose ideas of certain parts of London were all inverted; of another, who placed Paris north of London; of thirty well-informed young men, “about eighteen were under the impression that, while the sun rises in the east, the stars rise in the west, from having learned that the sun has a proper motion among the stars; and the author believes that there are few educated men who have not grown up with some curious errors with reference to geographical facts, which have bothered them all their lives, and which they have found it to be impossible to get rid of.” This defect may account for some of the accidents that occur on railways and shipping.

#### ESTABLISHED ANATOMICAL WORKS OF GOETHE.

In looking through the “Goethe and Schiller Archive,” in Weimar, Professor Karl Bardeleben, of Jena, has discovered a series of hitherto unknown anatomical writings by the poet Goethe.<sup>2</sup> Dr. Bardeleben will report on his discoveries in detail in the next volume of the *Goethe Jahrbuch*; meanwhile, however, he has written a brief account of them for the *Anatomische Anzeiger*. The writings in question consist of three manuscripts of considerable length and importance, and a number of short notes. The first of the three

is the first draft of the famous essay on the intermaxillary bone, of the year 1784, announcing Goethe's discovery of the said bone in man, the absence of which had hitherto been regarded as one of the main marks which distinguish man from the lower animals. Besides the text, Dr. Bardeleben found a series of illustrative drawings (originally seventeen in number) and a bundle of notes containing the not yet published details of the relevant osteological conditions in a large number of higher and lower mammalia.

One of the most interesting items of the discovery is the letter in which Goethe announced his discovery to Soemmering, who was just on the point of complying with a call to Mayence. It runs thus: “With the sincere wish that the change of your abode may redound to your happiness, I send you some attempts at osteological drawings stitched together with a view of laying before you a little discovery which I believe I have made. If, however, I should be mistaken, and tell you only something already known instead of a novelty, as I believe, forgive me, for, though my occupations do indeed permit me to cast a glance at nature and at the books which teach us to know it, it is impossible, in my position, to be accurately informed of what others have discovered before us.” Not less interesting is the letter in which Loder, of Jena, the only professional anatomist who at once unreservedly recognized Goethe's discovery, congratulated him after reading the manuscript. “I return you,” he writes, “the essay most kindly communicated to me with the sincerest thanks. Its perusal has given me so much pleasure, and your precision in anatomical description as well as your insight into the physiology of the part have inspired me with so much admiration, that I quite seriously regretted in my anatomical enthusiasm that you are a minister and not a professor of anatomy. But you will answer me, as the Emperor Leopold answered a musician who, after his Majesty had played him something on the piano, threw his arms round his neck in ecstacy, and regretted that he had not become a musician: ‘We are not ill off as it is.’”

Besides the essay on the intermaxillary bone, Bardeleben communicates two anatomical essays, both unfinished, but showing that Goethe pursued his studies in comparative anatomy with far-sighted sagacity and with no less an ultimate aim than that of gaining a uniform basis for the conception of the various animal forms. The first of the two has reference to osteology in general. Only the first part, treating of the comparative anatomy of the skull in mammalia, is finished, and Bardeleben believes it to have been written in the summer of 1794. The second essay, treating of the forms of animals, was written at Breslau four years before, and throws much more light on Goethe's conception of the nature of comparative anatomy than the first. After careful study of these essays, Bardeleben concludes that the frequent assumption of Goethe having been a pre-Darwinian Darwinite must be subjected to strict criticism. “Whether or how far,” he says, “one is justified in designating Goethe as a forerunner of Lamarck or Darwin, I do not wish to discuss here in detail. It seems to me, however, after a thorough study of Goethe's works, especially these newly discovered ones, that he did not go beyond an ideal thought or constructed type, and that the idea of man's descent from lower animals, of a real blood relationship among the latter and between them and man, was far from him.”

## Correspondence.

[From our Special Correspondent.]

### INTERNATIONAL CONGRESS OF HYGIENE AND DEMOGRAPHY, MEETING AT LONDON.

PRELIMINARY ARRANGEMENTS. — OPENING. — ADDRESSES OF DELEGATES. — ADDRESSES OF PRESIDING OFFICERS IN SECTIONS. — DEATH-RATE IN ENGLAND AND INDIA. — SPREAD OF EPIDEMIC DISEASES. — TRANSMISSION OF CHOLERA. — ETIOLOGY OF MALARIA. — RABIES. — SCHOOL-CHILDREN. — TOWN FOGS, ETC. — OPEN AIR SPACES. — SEWAGE DISPOSAL.

LONDON, August 21, 1891.

MR. EDITOR:— In the following notes upon the great gathering of public sanitarians from all parts of the world, I shall not attempt a full account of proceedings, but shall give an outline only of such matters as appear to be of special sanitary importance. It would require the possession of omnipresent powers to detail the valuable proceedings of the ten different Sections upon Preventive Medicine, Bacteriology, The Relation of Animal Diseases to Man, Infancy and School-Life, Chemistry in Relation to Hygiene, Architecture in Relation to Hygiene, Engineering, Naval and Military Hygiene, State Hygiene, and Demography.

The meeting of the British Medical Association at Bournemouth a few days previously, undoubtedly lent increasing interest to the Congress of Hygiene. The total number of persons who registered as delegates and members of the Congress, fell but little below 3,000. The Massachusetts Medical Society, the State, and the State Board of Health were represented by Drs. Wyman, Lyman, Drown, Prince and Abbott. Delegates were also present from New York, Maine, Michigan, Minnesota, Iowa, Kansas, and from the United States Army.

The preliminary arrangements for the Congress have been very thoroughly and successfully carried out. The place selected for the meetings is at Burlington House in Piccadilly, a location which is convenient and accessible from its proximity to many principal railway stations and hotels.

The opening meeting was held on Monday afternoon, in St. James Hall, which was crowded to its utmost, unusual interest undoubtedly being given to the meeting by the presence of His Royal Highness, the Prince of Wales, who is President of the Congress.

The meeting was opened by Sir Douglas Galton, who presented the report of the Permanent International Committee, briefly outlining the objects of the Congress.

The opening address of the Prince of Wales had the merit of brevity and good common-sense. He was followed by Dr. Brouardel, of Paris, President of the Permanent International Committee, who eulogized Jenner and Pasteur. Dr. Von Coler, Director-General of the Prussian Army, followed, his address being mainly devoted to the diminution of the death-rate in the Prussian Army, the actual decrease being represented by the difference between a death-rate of 6.9 per cent. of the strength in 1868, to 2.3 per cent. in 1888. Malarial fever, spinal-pox, dysentery and typhus fever have nearly disappeared from the list of diseases of actual occurrence in the army. He was followed by Dr. Roth of the German Government, and Professor Corradi of the Italian Committee, each of whom addressed the Congress very briefly.

M. Josef Kórosi, of Buda-Pesth, one of the foremost of living statisticians, confined his remarks to the history of Demography, a word which has proved quite a puzzle to the London daily papers. M. Kórosi's definition, however, was sufficiently clear. He stated that Demography as a branch of science, undertakes to investigate the laws which regulate the life, the increase and the decrease of nations. It comprises three parts: Statistics of natality, of mortality (including the measurement of the duration of human life), and the increase of population. The meeting closed with a vote of thanks to the Prince of Wales, offered by Sir James

Paget, seconded by Dr. Buchanan of the Local Government Board, and adopted by the audience with hearty cheers.

In the evening a dinner was given to a large number of guests by Sir Andrew Clark at the Royal College of Physicians; and in this connection I ought to add that all of the entertainments, excursions, dinners and receptions which have been given to the delegates and members of the Congress have been so well and so successfully managed as to add very largely to the pleasures of the week, and gave evidence of the unbounded hospitality of the patrons, as well as of all who were concerned in the general management.

In the Section upon Preventive Medicine, on Tuesday, Sir Joseph Fayrer, presiding, opened the meeting of the Section with an excellent address, in which he outlined the general history, the scope and objects of Preventive Medicine, dwelling at some length upon the reduction of the death-rate in England and in India.

Surgeon-General Cunningham's paper on the "Mode of Preventing the Spread of Epidemic Diseases from one Country to Another," presented three methods of work: Quarantine, medical inspection, and sanitary improvement. Taking cholera as an illustrative type of epidemic disease, he condemned quarantine both on land and on sea, and approved of each of the other modes of prevention, especially that of sanitary improvement.

Inspector-General Lawson presented the subject of "The Transmission of Cholera from one Country to Another," advocating the ancient (and hazy) theory of atmospheric influence. A lively discussion ensued, in which the English authorities generally condemned quarantine as useless. Opposite views, however, were strongly maintained by many foreign delegates.

In the Section upon Bacteriology, after a brief opening address by Prof. Lister, much interest was shown in the paper by Prof. Laveran, upon the "Etiology of Malaria." In this paper the author detailed the characteristics of the hematozoön which he had already described in 1880. Prof. Hneppce, of Prague, presented the subject of the "Bacillus of Asiatic Cholera," and the discussion which followed was participated in by Drs. Klein, Gruber, and others, who took different views of the subject.

In the Section upon "The Relation of Diseases of Animals to Man," the principal topic of discussion upon the first day, was Rabies. Dr. Roux, of the Pasteur Institute, read a paper upon the results obtained at the Institute in the preventive treatment of the disease, and advocated very earnestly the methods there employed. Dr. Fleming, F.R.C.V.S., in his paper on "The Propagation and Prevention of Rabies," advocated suppressive sanitary police measures, as follows, in the order of their importance:

- (1) The destruction of all dogs that are rabid, or suspected of being rabid.
- (2) The seizure and, if need be, the destruction of all ownerless and wandering dogs.
- (3) All other dogs to wear a properly constructed and well-fitted muzzle during the prevalence of rabies, and also for a period equal to the longest interval of latency after the malady has been suppressed.
- (4) The imposition of a tax on all dogs.

In conclusion, Dr. Fleming stated his belief in the possibility of stamping out the disease by strict measures, such as he had outlined, and said that it would only exist in those countries which do not desire to get rid of it.

An interesting discussion followed, in which many facts came to light. Dr. Hime, of Bradford, said that in England muzzling, as carried out, was very much of a farce. For example, in York, the dogs on one side of a street were muzzled and on the other side (in a different district) they were not.

Dr. Drysdale said that while the medical profession in England objected to the establishment of a Pasteur Institute there, they were very willing to avail themselves of the advantages of the institute at Paris.

In Sir Henry Simpson's remarks, he strongly objected to the carrying out of any restrictive measures by muzzling,

in consequence of the interference with hunting and sporting. He warned the Section that any appeal in England for legislation upon the subject, having muzzling in view, would be in vain. (Sportsman's pleasure, *versus* the protection of human life.)

Professor Ostertag, of Berlin, cited the experience of Germany, where the laws are very plainly effectual in suppressing the disease. It is of very rare occurrence in Germany except upon the borders of other countries. In Berlin all dogs wear muzzles, and a case of hydrophobia has not been reported for ten years.

Dr. Nocard, of Paris, gave some further details of the French method of preventive treatment as applied to domestic animals, especially sheep. He expressed himself as entirely in accord with Dr. Fleming. He also said that it is undoubtedly true that muzzling diminishes rabies, but it is clear that the result is only indirectly due to the muzzle. Never has the muzzle hindered a rabid dog from biting. When one has seen a rabid dog break his teeth and even jaws on the bars of his cage, one understands that the dog would not retain one minute any muzzle that one may have been able to place upon him before the disease broke out. But the muzzle has the advantage of showing clearly to the police the dogs which have escaped from the house, or have no home, or who are not the objects of supervision. It is from this class that most rabid dogs are furnished. To seize and take them is to suppress the disease. One would get at the same result by ordering that every dog in the public street should be held in leash. This is what was done in Paris in 1888: 125 mad dogs were observed in the month of April. The prefect of police obtained an order as above. The measure was only applied six weeks, yet it sufficed to reduce from 125 to 25, the monthly number of mad dogs for the last half of the year 1888. There is no necessity for new measures to suppress rabies. It suffices to have the will, and to apply rigorously the measures prescribed in all civilized countries.

The Section upon Infancy, Childhood, and School-Life was very fully attended, and many ladies were attentive visitors in this Section. Dr. F. Warner, F.R.C.P., presented a paper on "The Scientific Observation and Study of Children in School, and the Classes into which they may be Grouped." His classification was based upon observations upon 59,027 school children, and was briefly summarized as follows:

(1) Children well made, with a nervous system acting well, and average or bright at school-work. Of these there were among the 59,027 seen—boys, 21,315; girls, 19,536; total, 40,851. Such pupils are the average or normal, hence they do not appear further in the tables. It is seen here, as in most other cases, that the girls are better than the boys. In this work search was made for the abnormal and pathological. Scholarship would be most advantageously given to the best made children.

(2) A group similar to the last, but slow at lessons (referred to by teachers), that is, children presenting no defects to the observer who does not use mental tests.—It is important to differentiate such pupils from those with defective brain conditions. Some children's bodies and brains are well developed and sound though presenting no present faculty for school lessons, as the teachers' evidence shows. The mental examination and history may, on the other hand, show grave defects in intellectual and moral faculty. Many of this group were "eye cases," some "cripples," several were presented by the teachers, not having been noted by us. An analysis will be given in the full report.

(3) Cases presenting defects of development of the body of various kinds. It is not intended to represent children as exceptions from an educational point of view because some defects are present.

(4) Cases presenting abnormal nerve signs. Their signs may vary in two directions; the one group is associated with low development, the other with delicacy and nervousness.

Certain groups of children are best defined by the association of two or more physical conditions.

(5) Cases presenting defect in development and abnormal nerve signs.—Boys, 1,975; girls, 1,096; total, 3,071. Such children are usually dull at work, and are often at low nutrition.

(6) Cases presenting defect in development and abnormal nerve signs, also indications of low nutrition.—Boys, 412; girls, 381; total, 793.

(7) Eye cases. Obvious defects, such as squint or disease were recorded, but no tests were applied to detect errors of vision or refraction.

(8) Deaf or partial deaf.—Boys, 34; girls, 33; total, 67. Tests for hearing were not generally used, but when a child was found deaf it was noted.

(9) Cases crippled, deformed or maimed.—Boys, 157; girls, 84; total, 341. These children varied greatly. Many are partially incapacitated for life, others only temporarily, some are mentally dull, others bright; they also differ greatly in physical health and strength.

(10) Epileptic.—Boys, 32; girls, 23; total, 55. These cases were asked for in every school. Any case with a history of epilepsy or fits was recorded for what it was worth. It would appear that most epileptic children are frequently absent from school.

(11) Cases selected as exceptional in mental status.—This group includes cases where the results of observation coincided with the teacher's opinion as to mental defect; it includes many imbeciles, obvious brain defects and disease, while less serious cases are also given. It is difficult to define what physical conditions alone indicate the child as unfit for average training, and an arbitrary attempt to do so must fail. Speaking generally, classes 5 and 6 need special attention in school, and should be known to the managers.

(12) Children delicate, pale, or thin (low nutrition).—This condition shows a high degree of correlation, with defects in development and nerve signs, also with mental dullness. No inquiries were made in day-schools as to the feeding of the children. The 2,003 children with low nutrition, presented the following co-existing conditions: Defects in development, 1,459; abnormal nerve signs, 1,233; defects in development and abnormal nerve signs, 793; dull in school, 797.

The study of children in school.—The general outcome of this work indicates the advisability of studying the pupils in two ways: (1) by mental tests, and (2) by physical examination or inspection. For the gain of direct scientific knowledge it is desirable to note all departures from the normal types. It appears to be a great gain to note, not only points in development and physiognomy, but also the nerve signs indicated; those postures or balances and movements or actions which were noted as signs were selected after much labor in observation, analysis, and comparison, and they seem well suited for the purpose in hand. They are readily recognized, and can easily be taught by means of casts, diagrams, and demonstration.

Physical examination by inspection is useful (1) as a means of selecting cases for special mental report, (2) as supporting a report founded on mental tests only. The double mode of inquiry is specially necessary to detect certain cases; the mental test alone would leave out of view those nervous children who suffer much, but are usually bright at work and interested in it, and tend to pass the standards quickly; on the other hand, grave mental defects may occur with brains good for all other functions.

The paper received much commendation from the various members who took part in the discussion. Among other important communications to this Section on Tuesday was a paper by Dr. Jacoby of New York, on the "Employment of Children in the United States," in which he paid special attention to the progress made in the different States of the Union with reference to legislation upon this question.

In the Section upon Chemistry and Physics, Sir Henry Roscoe, presiding, addressed the Section at length upon the advances made in this branch of public hygiene, and its importance. He was followed by papers on "Town Fogs

and their Effects," by Dr. W. J. Russell; "The Air of Large Towns, and methods of its Analysis," by members of the Manchester Fields Naturalists Society, and upon "The Means at our Disposal for Preventing the Emission of Smoke from Factories and Dwelling-houses," by Mr. A. Fletcher of the Local Government Board.

In the Section upon Architecture the time was occupied by the opening address of the President, Sir A. W. Blomfield, and by a paper by the Earl of Meath, on "Open Spaces."

Granting that fresh air and open spaces are needed for the health of the people of large towns, he proposed the following methods of satisfying this need: (1) A systematic acquisition and preservation of land for public recreation, in connection with the towns and in relation to their growth; (2) Increased facilities for taking people from the towns into the country. In the towns themselves the governing bodies—the councils—should lay down and should carry out some such rule as the following: That public recreation grounds should be provided in each parish, in proportion to the number of its inhabitants.

The paper was very fully and thoroughly discussed.

In the Section upon Engineering in its Relations to Hygiene, Sir John Good, the President, gave the opening address. Among other facts which he presented, he stated that the following works have been executed for the special purpose of improving the health of London.

The main intercepting and principal branch sewers which have been constructed for the conveyance of the sewage of London to the two outfalls into the River Thames, at Barking and Crossness respectively, measure about eighty English miles.

Since the year 1856, when the now extinct "Metropolitan Board of Works" was formed, there has been expended on the main drainage works alone the sum of nearly £6,000,000, or \$30,000,000.

As a by no means unimportant factor among the changes which, in modern times, have resulted in the better health of our capital city, a reference to the supply of water of improved quality, and in larger quantity must not be altogether omitted. Up to the end of 1890 the several companies (eight in number) had expended upon works for the supply of water to London, a sum very closely approximating to £15,000,000, or \$75,000,000.

The average quantity of water delivered last year to the inhabitants of London, for domestic purposes alone, was 24.75 gallons per head of population per diem, and in respect to quality but little, if at all, surpassed by that supplied to any other city in Europe; this water is conveyed through pipes, the united length of which is about 1,760 miles.

The total volume of water delivered for domestic purposes only in 1890 was 64,000,000,000 gallons. For raising this large quantity the companies employed no less than 184 steam pumping engines, having an aggregate of 21,659 horse-power.

Whilst admitting that great benefits have accrued from the extensive drainage works which have been executed, and the large expenditure that has been incurred for improving the health of London, it cannot yet, by any means, be said that all has been accomplished which might be done in this direction. Nor will it be possible to say as much so long as the sewage of the metropolis is allowed to flow into any part of the Thames without previous purification by the most perfect method as yet known, that is, *by being filtered through sand*. The only alternative would seem to be the conveyance of the sewage to the sea-coast beyond the mouth of the estuary of the Thames.

Professor H. Robinson read a paper on "Sewage Disposal in relation to Water-supply and River Pollution," in which he recommended the placing of rivers under continuous chemical and engineering observation (a practice which has fortunately been rendered practicable in Massachusetts by recent legislation).

Professor Pacchiotti, of Tunis, presented the subject of "Town Drainage in Italy," in which he submitted the following essential principles for adoption: (1) Every town

must select that form of sewage disposal which is best adapted to its own circumstances; (2) *The tout à l'égout* system most clearly approaches perfection, and should be adopted by all towns which have a good water-supply and approved gradient; (3) Towns possessing suitable soil in or near a town, should establish sewage farms; (4) Unless absolutely unavoidable, sewage must never be allowed to flow into water-courses.

Other papers were read by Baldwin Latham, C. E., on "Sanitation in India"; "French and English Systems of Sewage," by Jas. Lemon, C. E.; and "The Sanitation of Mining Settlements."

In the General Division of Demography, having one Section only, Sir Francis Galton gave the opening address, in which he dwelt largely upon the relative fertility of different races and their tendency to supplant one another under different circumstances. He said, in conclusion, that the improvement of the natural gifts of future generations of the human race is largely, though indirectly, under our control. We may not be able to originate, but we can guide. The processes of evolution are in constant and spontaneous activity, some pushing towards the bad, some towards the good. Our part is to watch for opportunities to intervene by checking the former and giving free play to the latter. We should distinguish clearly between our power in this fundamental respect and that which we also possess of ameliorating education and hygiene. It is earnestly to be hoped that demographers will increasingly direct their inquiries into historical facts, with the view of estimating the possible effects of reasonable political action in the future, in gradually raising the present miserably low standard of the human race to one in which the Utopias in the dreamland of philanthropists may become practical possibilities.

After reading his inaugural address, Mr. Galton called upon Dr. Ogle, M.D., F.R.C.P., to read his paper on "The Relation of Occupation to Disease and Mortality."

Dr. Ogle contributed valuable statistics from English sources in which the following causes were given for differences in mortality in different occupations:

(1) Working in a cramped attitude, and especially in one that interferes with the action of the thoracic organs; (2) Overwork, and especially sudden muscular efforts and strains; (3) Dealing with noxious substances, such as lead, phosphorus, mercury, infected hides, etc.; (4) Working in ill-ventilated and overheated rooms; (5) Alcoholic excess; (6) Liability to accident; (7) Exposure to inhalation of dust of various kinds.

These causes were severally considered, and statistical tables given illustrating their action.

The mortality of dealers in liquor was specially considered, and was shown to be in the ratio of 1,521 to 1,000, as compared with men in other occupations.

(To be continued.)

## BOGUS MEDICAL COLLEGE IN WASHINGTON.

TACOMA, WASH., August 27, 1891.

MR. EDITOR:—Attention has been recently drawn, through the columns of your valuable journal, to the alleged medical college (Washington Biochemic) recently established at North Yakima, Wash. The enclosed article clipped from the Tacoma News, and written by me, as ex-president of the Pierce County Medical Society, will throw some light upon the inception and fate of this ephemeral fungus growth. "Professor" Carey was fined fifty dollars and costs, for illegal practice of medicine, by Judge Curry, of Spokane.

The proportions of the concern can be better understood if you tell your readers that a fire which destroyed five hundred dollars' worth of stuff (at retail prices, profits six hundred per cent.) nearly bankrupted the "institution," and that "Professor" Gans is a truck farmer on a three-acre lot.

Yours truly,

J. A. BEEBE, M.D.

## RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, AUGUST 29, 1891.

Cities.	Estimated population for 1890.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from					
				Infectious diseases.	Consumption.	Diarrheal diseases.	Typhoid fever.	Diphtheria and croup.

Deaths reported 2,821; under five years of age 1,374; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 291, consumption 293, lung diseases 151, diarrheal diseases 571, typhoid fever 75, diphtheria and croup 58, whooping-cough 24, scarlet fever 21, malarial fever 19, cerebro-spinal meningitis 11, measles 8, erysipelas 1.

From whooping-cough Pittsburgh 7, Chicago 5, Philadelphia, Boston, Milwaukee, Washington and Lowell 2 each, New York and New Orleans 1 each. From scarlet fever New York 9, Chicago 5, Philadelphia and Cincinnati 2 each, Boston, Milwaukee and Washington 1 each. From malarial fever New Orleans 3, New York 1, Baltimore 3, Philadelphia 2, Nashville 1. From cerebro-spinal meningitis New York, Chicago and Worcester 2 each, Boston, Washington, Cambridge, Chelsea and Taunton 1 each. From measles New York 3, Chicago and Pittsburgh 2 each, Portland 1. From erysipelas Cincinnati, Pittsburgh, Milwaukee and Worcester 1 each.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,105,108, for the week ending August 25th, the death-rate was 18.0. Deaths reported 3,252; acute diseases of the respiratory organs (London) 157, diarrheal 340, whooping-cough 70, measles 12, diphtheria 31, fever 32, scarlet fever 41.

The death-rates ranged from 8.8 in Halifax to 26.6 in Sunderland, Birmingham 15.5, Bradford 17.3, Hull 18.9, Leeds 17.5, Leicester 21.6, Liverpool 22.4, London 17.8, Manchester 18.5, North Ham 15.9, Sheffield 20.0, Wolverhampton 14.5. In Edinburgh 15.9, Glasgow 18.5, Dublin 20.6.

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 29, 1891, TO SEPTEMBER 1, 1891.

Leave of absence for fifteen days is granted Surgeon J. V. D. Mendenhall, U. S. Army.

Leave of absence for twenty-five days is granted Major James P. Keefe, U. S. Army.

Leave of absence for one month, to commence on or about September 3, 1891, is hereby granted Captain Adrian S. Polakoff, assistant surgeon.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING SEPTEMBER 5, 1891.

HOWARD WELLS, surgeon, ordered to temporary duty in the Bureau of Medicine and Surgery.

S. H. DICKSON, surgeon, detached from the practice ship "Constellation" and wait orders.

L. W. CURTIS, passed assistant surgeon, from the "Constellation" and to the Naval Academy.

W. H. RUSH, passed assistant surgeon, ordered to the U. S. S. "Yantic."

H. G. BEYER, passed assistant surgeon, detached from the "Yantic" and granted two months leave.

ROBERT BOYD, assistant surgeon, from the U. S. S. "Dale" and to the Marine Rendezvous, Boston.

## VIRCHOW TESTIMONIAL FUND.

The following, final, statement is made of the contributions received by the American Committee, all of which have been forwarded to the Treasurer of the German Committee —

Amount previously acknowledged	\$1,124.00
Through William Osler, Baltimore	211.00
" William Pepper, Philadelphia	107.00
Gustav Barmgarten, St. Louis	45.00
John S. Billings, Washington	80.00
Additional through J. T. Whitaker, Cincinnati	30.00
" from New York, through W. H. Draper	10.00
From Henry M. Lyman, Chicago	25.00
" John A. Gordon, Quincy	5.00
" George Ross, Montreal	5.90
" James E. Graham, Toronto	10.00
Interest	8.69
Total	\$1,660.69

Reginald H. Fitz, M.D., for the Committee.

## APPOINTMENT.

JOHN F. CROSTON, M.D., of Haverhill, Mass., has been nominated by Governor Russell, as medical examiner in his district to succeed Dr. William Cogswell, of Bradford, deceased.

## ERRATA.

In the article on "Sarcoma of the Nose," by Dr. J. Payson Clark, in the last number of the JOURNAL, there were two errors. On page 239, first column, fourth paragraph, fourteenth line, "the *snare* being turned slowly" should read "the *scissors* being turned slowly." On page 241, second column, third paragraph, twelfth line, *microscopy* should read *rhinoscopy*.

## DEATHS.

GEORGE E. LIVERMORE, M.D. (Dart. 1884), M.M.S.S., of Lowell, died September 4th.

W. W. A. SPOTSWOOD, M.D., U. S. N., died in Mobile, Ala., September 7th, aged eighty-five. He was appointed assistant surgeon in the Navy in 1828, and surgeon in 1838, and retired in 1861.

HORACE HATCH, M.D., died in New Haven, Conn., August 28th. He had practised medicine in Washington for twenty years, retired in 1884.

J. R. SPEER, M.D., died in Pittsburgh, September 6th, aged ninety-five.

DANIEL PARKER, M.D., of Fulton, N. Y., died August 25th, aged fifty-two.

JOHN F. KEEFE, M.D., of New York, died August 26th, aged forty-six.

## BOOKS AND PAMPHLETS RECEIVED.

A Manual of Practised Hygiene. By the late Edward A. Parkes, M.D., F.R.S., Professor of Military Hygiene in the Army Medical School. Eighth edition. Edited by J. Lane Nott, M.A., M.D., etc. Philadelphia: P. Blakiston, Son & Co. 1891.

Diseases of the Nasal Organs and Naso-Pharynx. By Whitfield Ward, A.M., M.D., etc. New York and London: G. P. Putnam's Sons. 1894.

The Electrical Treatment of Fibroid Tumors, with an Analysis of Forty-six Cases. By G. Betton Massey, M.D. Reprint. 1891.

## Address.

THE HEALTH AND LONGEVITY OF MEDICAL MEN.<sup>1</sup>

BY FRANCIS MINOT, M.D.

MR. PRESIDENT AND GENTLEMEN: In thanking you for the honor you have conferred upon me by inviting me to address you on the occasion of your annual meeting, I need hardly allude to the advantages, both to the profession and to the community, of an association like this, including so many of the most eminent medical men of the State. In no way is the science and practice of medicine better promoted than by the frequent intercourse of physicians, who are thus enabled to contribute to the common stock of professional knowledge the results of their personal observation on the nature and the course of the various diseases to which we are liable, as well as their experience in the modes of treating them. Such meetings are also valuable as a means of maintaining the dignity of the profession, of making it worthy of the respect of the public, by showing that the great object of medical science is the prevention and cure of disease and the relief of human suffering. I need not dwell upon the pleasure of personal intercourse and social enjoyment which an occasion like this affords.

In offering for your consideration some remarks upon the subject of the health and longevity of medical men, I shall endeavor to point out the advantages we possess over other professional men, as well as the dangers to which we are especially exposed, and the best means of their prevention.

It would be reasonable to believe that the health of professional men, that is of ministers, lawyers and doctors, ought to be as good as, if not better, than that of the rest of the community. They have good food, good clothing and good shelter. They are generally fully occupied, but only exceptionally overworked. They are usually free from the trials and anxieties of political life. Money-making is not often a passion with them. Comparatively speaking, they are but little subjected to temptations of excess and immorality, which are the sources of a considerable part of the diseases of mankind.

Both observation and investigation confirm this impression; and in respect to longevity, we find that lawyers, ministers and doctors rank among the highest in the different classes of society. Some interesting figures relating to this subject are contained in the Massachusetts Registration Report for 1885, prepared by Dr. Frank Wells (the latest which I have at hand), and, at the risk of wearying you with such dry details, I will venture to quote them. The average age at the time of death of nearly 230,000 persons whose occupations were specified (including only those individuals who were over twenty years old at the time of death), during a period of forty-two years and eight months, in the State of Massachusetts, was 51.82 years. Now we find that, of these 230,000 persons, the clergymen, professors, lawyers and physicians have a decided advantage over all the others. Dr. Wells's tables include a total of 4,495 such persons, and their average age at the time of death was over fifty-nine and one-half years, distributed as follows: judges and justices averaged 66.17 years; clergymen, 60.31 years; pro-

fessors (classified as distinct from teachers), 58.44 years; physicians, 56.51 years; lawyers, 56.41 years. Thus we see that, in respect to longevity, professional men, in a community in which the physical comforts of life are probably as evenly distributed as in any other part of the world, have but little to complain of.

Comparing the duration of life in the three professions of divinity, law and medicine (in Massachusetts), we find, according to Dr. Wells's report, that clergymen (averaging 60.31 years) have the advantage of about four years over the others. (I leave out the question of the average for judges and justices, which being based upon an aggregate of only forty-six persons is hardly trustworthy.) Professors (classified as distinct from teachers), with an average of 58.44 years, come very near ministers; while physicians and lawyers, who are almost exactly alike in their expectancy of life (56.51 years and 56.41 years respectively), are lowest in the scale.

These ratios differ somewhat from those which obtain in England. The clerical profession stands there, as with us, highest in longevity, but the medical men are much the lowest. Dr. William Ogle, in a valuable paper read before the Royal Medical and Chirurgical Society, a few years ago, states that in the years 1880, 1881 and 1882, the ratio of the *mortality* of the medical profession was 25.53 per thousand living persons; of the legal profession, 20.23 per thousand; of the clerical profession, only 15.93 per thousand living. Such a difference between the mortality of medical men in England and in this country is very remarkable, and cannot easily be accounted for. Possibly it may not be correct, the error being due to the smaller aggregate of individuals reported with us, compared with the very large numbers upon which the English statistics are based. At any rate, the duration of life of medical men in Germany corresponds very nearly with that in the State of Massachusetts. According to Dr. Birnbaum,<sup>2</sup> the average age at the time of death of 2,000 physicians was 57.8 years.

The question is often asked, How do physicians escape contagious diseases, to which they are so much exposed? According to Dr. Ogle they do not escape them (in England), since in most contagious maladies, such as scarlet fever, diphtheria and typhus (ship) fever, their mortality is in excess of that of other men; though in small-pox much less, owing to their careful protection by vaccination. In all lung diseases, especially consumption, their mortality in England is also much less than that of other men, probably owing to their open-air mode of life. The excess of their general mortality is, according to Dr. Ogle, probably to be accounted for in great part by their laborious lives, by loss of sleep, by great responsibility and anxiety, by irregularity of meals; and, I may add, by want of sufficient intervals of relaxation and of long vacations. These unfavorable conditions of the professional life do not, however, apply especially to English physicians; they are the same with practitioners in all parts of the world, and the deaths from contagious and infectious diseases, such as diphtheria, ship fever, typhoid fever, etc., are very considerable among physicians in this country, especially among the younger members of the profession, who spend much time in the insanitary dwellings of the poor.

<sup>1</sup> Address delivered at the Annual Meeting of the Rhode Island Medical Society, June 11, 1891.

<sup>2</sup> Die Lebensdauer der Aerzte, Deutsche Med. Zeitung, No. 26, 1890.

On the whole, I am inclined to share the belief of Dr. Charles K. Mills, as stated in an interesting (Toner) lecture delivered at the Smithsonian Institute, that physicians, in this country at least, are less liable to disease than members of other professions, in spite of broken rest, irregular meals, bodily fatigue and much responsibility, owing to their active life, much of which is spent out of doors, and to their knowledge of health and disease, which they are able to apply to their own behoof.

The majority of our profession depend for their subsistence upon work, and most of us derive from our labor a great amount of happiness. The problem, therefore, is how to accomplish the greatest amount with the least injury to health. This is best attained by intervals of relaxation. Moreover, the *quality* of the work accomplished often depends upon the amount of rest allowed, and upon a habit of occasionally withdrawing the mind as completely as possible from business cares during the intervals of rest. It is wise to have some supplementary occupation, wholly different from professional labor, to which we can turn, from time to time, for refreshment. The cultivation of flowers, the study of some branch of natural history or other science, the pursuit of some subject in history, literature or art, etc., furnish an agreeable change from our regular employment, to which we can afterwards return with increased power of application. Many great workers avail themselves of this alternation of employment, often seeking the very opposite to their professional duties for refreshment. I knew an eminent justice of the Supreme Court of Massachusetts, who, during the summer circuit, after a hard day's work in court, would retire to his bedchamber with a candle, and spend the evening in reading a sensational novel; and we all know how Macaulay delighted in reading works of fiction during his moments of leisure. Sir John Lubbock, well known for his researches in anthropological, botanical and entomological subjects, is, by profession, a banker in London, busily occupied in financial affairs, and also a member of Parliament.

Besides occasional short alternations of work and relaxation, few things are of more benefit to the health of professional men than a complete vacation from business once a year. This should, if possible, embrace some weeks spent away from home, for the sake of a complete change of surroundings. The late Benjamin R. Curtis, one of Massachusetts's greatest lawyers, used to say that he could easily accomplish his year's work in nine months, but not in twelve.

In-sufficient exercise, especially walking, may be mentioned as one of the causes of ill-health among physicians. Many of us spend almost the whole day, and sometimes many hours of the night in driving, which affords but a poor substitute for leg-exercise. I hope the use of the bicycle will soon supersede, to some extent, driving; and that gymnastic exercise, which is also a valuable means of promoting the health, will become popular with doctors.

Another serious interference with health in our profession is inefficiency of sleep. Every physician should, if possible, secure at least seven hours of rest at night; and when this is interrupted, he should make up for it, at least in part, in the daytime. Happy the doctor who acquires the habit of sleeping at odd moments, when his nights are disturbed by his duties toward his patients.

In conclusion, permit me to illustrate the suggestions which I have ventured to offer by citing three examples of laborious lives. In the first one, owing to neglect of precautions for the preservation of health, the result was disastrous, both to health and life. In the two others, in consequence of judicious alternations of labor and recreation, an immense amount of work was accomplished without injurious consequences.

The first case I shall quote illustrates so clearly the folly of incessant work without any relaxation that it needs no comment. It is that of an eminent London physician, the late Dr. Golding Bird, by whose death the profession lost one of its most brilliant members. It is related by his friend, Dr. Routh, in the following words: "I well remember a conversation I had with the late Dr. Golding Bird, a few months before his death. He was then in the zenith of his popularity, and recognized by all as one of the ablest of our London physicians. I called upon him one morning with a relative to consult him. Several other medical men had preceded me; his rooms were full; and I had to wait three hours ere I could gain admission to his study, and consult him about the case. I congratulated him on his success in practice. 'Yes,' he said to me, 'you are right; but I wish, nevertheless, to make your remark a text for a little parting advice. You see me, at a little over forty, in full practice; my rooms are full, and I am making my several thousands [pounds] per annum (I think he said seven), and if I die to-morrow, I do not leave as many hundreds to my family. All this I have done by sheer perseverance, unceasing hard work, and no holiday. But I am to-day a wreck. I have fatal disease of the heart, the result of anxiety and hard work. I know I cannot live many months; and my parting advice to you is this. Never mind at what loss, take your six-weeks' holidays. It may *delay* your success, but it will *insure* its development. Otherwise, you will find yourself at my age a prosperous practitioner, but a dying old man.' Six months after this conversation he had put off this earthly tabernacle."

Few men ever accomplished more by dint of hard work than Charles Darwin, yet Darwin was a sufferer from ill health during the greater part of his life, so that he could only employ a few hours a day in writing, and those had to be systematically divided, with intervals of rest and exercise between. But he never wasted time during his hours of work. "He would often say that saving the minutes was the way to get the work done." He breakfasted at a quarter before eight, and went to work at once from eight to half-past nine, when he read his letters, or had them read to him, together with a part of a novel, till half-past ten. Then he worked till noon, or a little later. Riding or walking followed, then came lunch, after which he read the newspaper and wrote letters till three. Then resting on a sofa he listened to a novel, or some book not scientific. In the afternoon he worked from half-past four to half-past five. His actual literary work, therefore—(writing and reading), occupied only five hours, or sometimes five hours and a quarter, daily, besides his correspondence, which he usually dictated. But this did not include the whole of his scientific work, a considerable part of which consisted in experimental investigation of the habits of plants and animals, and which was much less fatiguing to him. "He was fond of listening to music, and

liked novels. Walter Scott, Miss Austen and Mrs. Gaskell were his favorite authors, who were read and re-read, till they could be read no more. It was a sure sign that he was not well when he was idle at any other times than his resting hours, for as long as he remained moderately well there was no break in the regularity of his life." Darwin died at the age of seventy-three years. His complaint seems to have been a functional derangement of the stomach, or possibly, gastric ulcer. He had frequent nausea and vomiting, and, at times, severe pain, by which he was greatly prostrated, and not rarely laid up for weeks, unable to do any work. Yet, by great regularity of life, and frequent intervals of complete rest, he accomplished an enormous amount of work.

Another prodigious worker was Dr. Littré, a French physician, best known as the author of the great French dictionary in four quarto volumes, and who was also eminent in several other departments of literature. The following description of his labors during the printing, only, of the dictionary (which required thirteen years) is given in his own words: "My rule of life included the twenty-four hours of the day and night, so as to bestow the least possible amount of time to the current calls of existence. . . . I rose at eight; very late, you will say for so busy a man! Wait an instant. Whilst they put my bedroom in order, which was also my study, I went down stairs with some work in hand. It was thus, for example, that I composed the preface of the dictionary. I had learned from Chancellor d'Aguesseau the value of unoccupied minutes. At nine, I set to work to correct proofs until the hour of our midday meal. At one, I resumed work, and wrote my papers for the *Journal des Savants*, to which I was, from 1855, a regular contributor. From three to six I worked on the dictionary. At six, punctually, we dined, which took about an hour. They say it is unwholesome to work directly after dinner, but I have never found it so; it is so much time won from the exigencies of the body. Starting again at seven in the evening, I stuck to the dictionary. My first stage took me to midnight, when my wife and daughter (who were my assistants), retired. I then worked on till three in the morning, by which time my daily task was usually completed. If it was not, I worked on later, and more than once, in the long days of summer, I have put out my lamp, and continued to work by the light of the coming dawn. However, at three in the morning I generally laid down my pen, and put my papers in order for the following day, that day which had already begun. Habit and regularity had extinguished all excitement in my work. I fell asleep as easily as a man of leisure does, and woke at eight, as a man of leisure does." He was past forty when he began this work; he was fifty-nine when he began to print the dictionary; he was seventy-two when he completed it, and he lived to be near eighty. He abstained from every kind of luxury and indulgence, *except one month in the year*, spent on the coast of Brittany. It was doubtless this vacation which chiefly helped to preserve his health during this gigantic work; but I think the diversion afforded by writing articles for the journals was also of some assistance.

Few of us will be called upon to undertake such labors as were achieved by each of these three men; yet, as a rule there is no profession which exacts so much work as ours. If I shall have called attention

to the importance of preserving our own health, while engaged in the task of restoring that of our patients, I shall not have spoken in vain.

### TYPHOID FEVER.<sup>1</sup>

BY WILLARD H. PIERCE, M.D., OF BERNARDSTON.

TYPHOID or Enteric Fever, from the variety and severity of its symptoms and from the fatality which attends many of its epidemics, is one of the most interesting and important diseases with which we have to deal. The disease is of interest from two standpoints: first, as regards the theoretical problems of its bacterial origin, etc.; second, and that with which I shall most particularly deal in this paper, from its clinical aspect.

Typhoid fever was not treated of as a separate disease until the present century, and its personality was not generally accepted until about the middle of the century. Since that time much has been written on this subject by able and scientific observers, and, considering my limited means for accurate, scientific work, it may seem presuming in me to attempt to deal with the subject. Nevertheless, as my clinical acquaintance with the disease has been considerable, and in carefully observing its course and termination certain beliefs have forced themselves upon me which are not in exact accord with the writings of many standard authors, I may be pardoned for presenting them for consideration.

The correct answer to the question "What is the exact etiological factor which produces the disease known as typhoid fever?" would be of more value than volumes written upon pathology and treatment. But, as a matter of fact, we do not know the exact nature of the poison which produces this disease. One thing seems to be established, namely, that the germ finds its best abiding place in decomposing animal matter. But I believe that it does not originate from the contents of cesspools and sewers, but in them finds the proper soil to develop its specific properties of producing typhoid fever.

The disease under discussion is eminently a disease of civilization. When a country or section of a country is first settled, malaria is the disease which predominates. But, as time goes on, and the accumulation of decomposing organic matter increases, the proper soil is made for the development of the typhoid germ, and malaria is displaced and enteric fever gradually becomes more prevalent.

In the recent epidemic which occurred in my vicinity the cause could be, in most instances, traced to the contamination of the drinking-water by water-closet sewerage. But there were hardly two cases which could be said to have received their poison from the same source. It seemed in some way the germs were disseminated through the air, but produced no disease except where they were first combined with decomposing animal matter, and then found their way into the drinking water of the unsuspecting victim. The increased prevalence of the disease in the autumn is undoubtedly due to the fact that the germ, wherever it may exist, becomes dried by the heat of summer, and,

<sup>1</sup> Read before the Massachusetts Medical Society, June 2, 1891, and recommended for publication by the Society.

in this condition, is easily carried through the air, and, having been combined with the proper reagent, so to speak, is rendered active and capable of producing a specific form of fever.

My first practical knowledge of the manner in which typhoid fever is propagated was gained while a student in Barlington, Vermont. This beautiful city with its perfect system of drainage (it being located on a hill-side), would seem to be a spot where one would be safe from the ravages of the typhoid germ. But, looking more closely, it would be seen that all the sewerage of the city was emptied in Lake Champlain and the water-supply for the inhabitants was pumped out less than one-half a mile from the opening of the main sewer.

Now, the fact that the people had for years been drinking diluted sewerage, and had not had typhoid fever, goes far to prove that the germ does not originate, *de novo*, from organic impurities. But, in the summer of 1884, a case of this disease was imported, and in the space of a few weeks a terrible epidemic swept through the city, causing the loss of many valuable lives. Of course, many examples like the above are familiar to you all. One of the most recent is the epidemic in Philadelphia, where, since January 1st, there have been about 1,500 cases, with 311 deaths;—the cause being, undoubtedly, the drinking of the sewer-polluted water in combination with the typhoid germ. In giving the result of my clinical observations, as to the immediate cause of typhoid fever, I would say, that I believe the disease is caused by a specific germ, but that this germ is not capable of producing the fever when first derived from the typhoid patient, but must undergo a change resulting from its combination with some substance found in decomposing organic matter.

Now, if this hypothesis be true, a great majority of cases of typhoid fever might be prevented by laws, giving the Board of Health in every community the power to compel every householder, whether in city or country, to see to it that the sanitary conditions are such as to render it impossible for drinking-water, or food or air to be contaminated with the emanations from the water-closets or sewers. It certainly is the duty of every one of us to instruct those under our care in the matter of sanitary arrangements, so that there may no longer exist, as there now does in a surprising number of cases, an almost direct communication between the well and the cesspool. This part of the subject is to be ably discussed in another department, so I will leave it with this brief allusion to the really most important part of the study of typhoid fever.

In discussing the diagnosis of enteric fever it can be said that, in many cases, a positive diagnosis cannot be made during the first, and, oftentimes, until the second or third week of the disease. The fever often departs from its typical course, and we must ever be on the alert and cautious as regards our diagnosis during the early days of a continued fever.

We often hear it said by the laity and sometimes, I am sorry to say, by members of the profession, that a simple "slow" fever has "run into" a typhoid. Of course a typhoid fever is typhoid from beginning to end.

Cases pass through their whole course without eruption, delirium, tympanites or iliac tenderness, and yet suddenly die from hemorrhage, and the autopsy shows the typical lesion of enteric fever.

In illustration of this part of the subject, I will report the following cases which occurred in my vicinity last fall:

The first patient whose case I will present was a laboring man about fifty years of age. My first visit was during the month of July, and the only symptoms were that he felt "weak and run down," as he expressed it. His temperature was normal, pulse 80, tongue lightly coated, bowels badly constipated, no appetite, urine high colored but normal in quantity. Surface of the body free from eruption. No case of continued fever had been under my observation for months. The man continued in practically this same condition for two weeks. He was able to be about the house and did some light work.

At the beginning of the third week a slight temperature showed itself, and, after two or three days, ranged 104° in evening and 102° in the morning. There was no diarrhoea, laxatives being necessary throughout the whole course of the disease. No tympanites, no delirium and no iliac tenderness.

I should have been obliged to show my ignorance of the nature of the malady, by calling the case one of "slow" or "bilious" fever (which, by the way, means nothing), had not the typical typhoid eruption shown itself at about the fourth week of the illness. Several successive crops appeared, demonstrating the nature of the fever.

The fever disappeared at the end of 42 days, counting the two weeks during which there was no rise in temperature. The man made a slow recovery. In this case there were absolutely no symptoms showing the disease to be typhoid fever until the eruption appeared, yet, given the proper soil in which to develop, the germs given off in the dejections from this patient might have produced an extensive and fatal epidemic of enteric fever. Our unfailing rule in cases of fevers, therefore, should be to thoroughly disinfect all discharges, whether or not the exact nature of disease be evident at first.

A second case I will briefly report here to show the unsatisfactory condition of our knowledge of continued fevers.

A man aged 40, newspaper editor. Had suffered more or less from attacks of malaria for two years previous to this illness. I was first called to him in August last, and, at my first visit, found an afternoon temperature of 104°; rapid pulse, loss of appetite and feeling of general *malaise*.

The patient was put in bed, on a milk diet, and full doses of quinine administered, with the idea that I had a case of intermittent to treat. The temperature, of course, was for a few hours lowered, but soon mounted up to a higher point than ever. The quinine had no effect on the course of the disease, although it was given a thorough trial.

This patient continued for six weeks with a fever ranging about 104° in the evening and 102° in the morning. There were no symptoms to indicate the exact nature of the fever. All the typical typhoid symptoms were absent except the curve of the temperature, which followed about the prescribed course. Yet, what was the disease from which this man suffered and barely made a recovery after one true relapse (caused by an error in diet) and a protracted convalescence? It certainly was not a true intermittent or remittent fever. Three physicians were called in consultation, and one said the case was remittent; one

that it was typho-malarial, and one that it was a bilious fever, whatever that may be.

This case serves to show in what a dilemma I, at least, find myself in the diagnosis of a continued fever possessing no distinctive symptoms. And these kinds of fevers are much more common than I believed while listening to didactic lectures or reading the accurate descriptions of the text books. I will cite one more case in this line.

This case was reported to the Franklin District Medical Society by Dr. N. P. Wood of Northfield, and the notes of the same have been kindly loaned to me. I will report in the doctor's own words:

"August 29, 1888, I was called to see Mrs. R. S., aged 42, married. She gave a history as follows: Had complained of general *malaise* for nearly a week; headache, loss of appetite, loose bowels and somnolence. I found her with a slightly coated tongue, anorexia, headache, but temperature and pulse normal. Her bowels moved from one to three times daily, while her usual condition was constipated. Color and odor of stools were normal. She said she had had similar attacks and usually recovered in a few days. Prescribed sponge bath and bitter tonic.

"In two or three days the headache, somnolence and loose bowels disappeared, but the anorexia, coated tongue and *malaise* continued.

"There was absolutely no tympanites, no tenderness over the abdomen and no rise of temperature. This condition continued about ten days, when I discovered the typical eruption of typhoid fever on the abdomen. This eruption continued in successive daily crops for about ten days more. This general condition lasted until September 22 (she was first seen on August 29), when she began to improve and went on to recovery in about the usual way after typhoid fever.

"Not once during the course of this sickness did I discover any departure from a normal temperature."

Dr. Wood reported another case which followed about the same course as the above, absence of a rise of temperature, etc. This patient died from the severity of the attack, and the autopsy showed the unmistakable typhoid lesion.

Now in my experience, the cases which are called atypical are more numerous than those which correspond to the description given in our standard text-books, and by medical instructors, as the usual course of the disease.

We who begin the practice of medicine to-day, have no method of learning the natural history of a disease but by the writings of those who have observed the clinical symptoms before us. One of two things, therefore, must be true: either typhoid fever has of late grown more mild and its symptoms more often depart from the supposed typical course, or else, we are dealing with a different disease. It seems that *writers* of to-day dare not depart from the older descriptions of the clinical history of typhoid, but I have *personally questioned* many physicians of extended experience and none of them are familiar with the symptoms (except in rare cases) as we are taught to look for them. During the past season I was brought in contact with many more than the usual number of cases which occur each year, but in only one instance did I observe what might be called a typical case. The symptoms most frequently absent are delirium, tympanites, iliac gurgling and tenderness, and, in many cases, the fever is not of a high range.

My conclusions in regard to this matter are these:

First: the disease now known as Typhoid Fever differs much from that described by the older writers, and the symptoms which were formerly thought to be invariable, are much less frequently present.

Second: the diagnosis of this disease is many times attended with extreme difficulty, and is generally impossible in the early stages.

Third: cases which seem extremely mild may suddenly develop dangerous symptoms, and the patient may die as a result of errors in diet or other indiscretions.

Fourth, and lastly: that much study is needed so we may properly classify fevers and avoid confusion.

I believe that from the study of bacteriology we shall eventually receive the required light on the subject.

Coming now to the treatment of this protracted and dangerous disease, it would seem that some radical measures must be instituted to destroy its activity.

But, although in no other disease with which we have to deal is the constant and careful attention of the physician more necessary, yet, I am moved to say, in no other malady is injudicious and indiscriminate use of drugs more productive of harm than in typhoid fever.

The patient must be under our watchful supervision, but, instead of standing ready to pour the heaviest guns of our medical battery upon the advancing disease, we should carefully watch the teachings of that almost unerring guide, *Nature*, and assist her with the most gentle means at our command. First, and most important of all, is the dietetic part of the treatment. Many cases need nothing more than rest in bed and a proper regulation of the diet. I would say here that in all cases the patient should not be allowed to be out of bed.

What is the proper diet for a typhoid patient? This is a most important question, and one much discussed. There has of late arisen a belief among a part of the profession (and, among these, many of our eminent men), that a more "liberal diet" should be allowed; that many patients die from lack of the proper amount of nourishing food. The patient is, therefore, given beef and mutton broths, and, indeed, solid animal food; also many other kinds of solid food.

In my opinion there are radical objections to this method of feeding a fever patient.

First: it is a physiological and clinical fact that when the temperature is above normal, the digestion of animal food goes on slowly, and, where the temperature is high, is not performed at all.

Second: there is formed a large, partly digested mass of fecal matter acting as an irritating, foreign body, augmenting the fever and other symptoms of the disease, and requiring for its expulsion an extra effort on the part of the already over-taxed powers of nature.

We are dealing with a disease whose primary lesion is in the intestinal canal, and the ideal food is one which will be most completely digested by the stomach and form the least waste matter. Now, we have just this ideal food supplied us in good, fresh cow's milk. And I believe clinical experience bears me out in saying that the best results are obtained by its judicious use.

I say judicious, for the well being of the patient depends, not upon the amount of milk *exhibited*, but upon the amount which is *digested* and *assimilated*.

And here, I believe, is the explanation of the ill results obtained by some physicians. A rule has been given that every patient must receive from three to six pints of milk in the twenty-four hours. So this exact amount is poured into the stomach without regard of its capacity for digesting it. Now, I have seen six ounces to be of infinitely more benefit to a patient than six pints would have been.

Our only rule should be to administer no more milk than can be readily digested and assimilated. The ill effect of animal food given to a seemingly mild case of typhoid fever, is shown by the following cases:

First, a young girl, aged 12 years; had reached the fourth week of the disease, the temperature never having risen above  $104^{\circ}$ , and much of the time only  $102^{\circ}$  in the evening. No bowel symptoms. The parents thought it was time to give something more substantial than milk, so called in consultation a physician who was of the same opinion.

Scraped, raw beef, placed between two thin layers of bread, was given to the patient. Intense pain followed the ingestion of the food, and, for a time, it seemed that death would ensue as a result.

In about six hours, however, the offending mass was ejected from the bowels in exactly the same condition as when taken into the stomach.

Case No. 2 has been referred to in speaking of the atypical forms of the disease. The case had run on to the sixth week, and had begun to convalesce, when, without my knowledge, solid food, in the shape of scraped beef, was given to the patient. Great distress followed and the patient suffered a genuine relapse, keeping him in bed a month longer. The beef was passed from the bowels unchanged.

I might report many more similar cases which occur to me as I am writing, but these two serve as a type of the cases I have seen treated with the "liberal diet."

In regard to the use of alcoholic stimulants in typhoid fever, I would say that I believe many lives are saved by the timely use of whiskey or brandy. To be of value, though, they should not be given until the advanced stage of the disease is reached, and only then when the irregular, wiry or dicrotic pulse indicates the impending failure of the heart. Stimulants should then be used freely and fearlessly. If given throughout the whole course of the fever, they prove of no value when we reach the real time of need.

In discussing the matter of treatment, nearly all writers consider the reduction of the temperature of the greatest importance, and base their prognosis upon, and derive their indications for treatment from the registering of the thermometer. Wilson in his great work says: "The main point in the management of enteric fever is to control the temperature." Bartholow, in his "Practice of Medicine," tells us that: "As the main point in the management of typhoid is to depress the temperature, the treatment directed to that end is the most important." Dr. George B. Shattuck, of Boston, in the "Reference Handbook," comes at the matter a little more gently, and, in speaking of the management of the pyrexia, says: "An evening temperature rising above  $103^{\circ}$  F. suggests the propriety of interference." In the face of these names, I hesitate to express my views on the subject. But I will say that I believe he who constantly keeps the thermometer in position and depends upon that as his guide in treatment, is simply watching one of the

necessary symptoms of the disease, and may not only overlook more important symptoms, but will be likely to do harm by the use of the powerful heart depressants which will produce at best but a transitory reduction of the temperature.

I do not believe in the general use of antipyretics in the continued fevers. All the remedies of this class are either primarily or secondarily powerful cardiac depressants. Therefore, in a fever of typhoid nature, they are certainly contraindicated. The temperature is, of course, reduced; but, unless held down by repeated doses of the antipyretic, it will mount higher than before. The seemingly good effect produced by such remedies as antipyrin, acetanilide and phenacetin is, I believe, due not to their antipyretic action, but to their analgesic effect.

They merely serve to mask the symptoms for a time, but it is impossible that they can serve as an anodyne to the conscience of the physician who fully understands their action, and who has in mind not altogether the momentary relief of a symptom, but looks much farther and seeks the ultimate good of the patient entrusted to his care.

A remarkable result from the use of digitalis in a case of typhoid is worthy of mention here. A boy, aged eleven, had been suffering from an attack of the fever for ten days. The morning and evening temperature were nearly the same, having been running for six days at an evening temperature of  $105.5^{\circ}$  and a morning temperature of  $104.5^{\circ}$ . The pulse 140 and irregular. Digitalis was administered in the dose of one minim of the fluid extract every four hours. After four doses of the drug had been administered, I was hastily summoned to his bedside and found him in a state of collapse, and the temperature during this time had dropped from  $105.5^{\circ}$  to  $97.5^{\circ}$ —a fall of eight degrees. The pulse was 40 per minute. I certainly reduced the temperature and pulse in this case, but never was I more pleased than when I was again able to see the temperature of  $103.5^{\circ}$  recorded. No more antipyretics was given in this case, which went on to a final recovery.

It may be proper to speak here of the use of the cold bath, although it is not correct to class this remedy as an antipyretic. The good results obtained by the use of Brand's method, or some modification of it, is most assuredly not by the antithermic effect alone, as some writers would lead us to believe, but by the energizing effect upon the nerve centres, produced by stimulating the peripheral nerves with cold water. The cold bath is of positive value in the treatment of typhoid fever, and the inconveniences and expense attendant upon its use should not cause us to withhold it from our patient, who stands in mortal danger and demands of us all possible aid at our command.

The method by which we may gain indefinitely more knowledge of the patient's condition is by a careful observation of the pulse.

The time-honored habit of pulse study and pulse counting should not be neglected. For, by that test of all *sphygmographs*, the trained *finger-tips*, a knowledge of the condition of the circulation, of the force and nature of the heart's action, can be obtained. Here we may get our indications for increasing the amount of food or for the administration of stimulants, and gain knowledge upon which to base our prognosis.

The thermometer is undoubtedly an addition to our armamentarium, but its use should not displace other

methods of study which are really of more value. Various specific methods of treatment have been advocated from time to time, but, from our present knowledge of the disease, such methods can be of no scientific value.

When we become acquainted with the nature and habits of the typhoid germ, then we will have a foundation upon which to build a specific treatment. Many of the advocates of some so-called specific treatment claim excellent results, and it will be seen that many remedies are of much use. But it will also be seen that most of those drugs which seem to favorably modify the course of the disease belong to one class, namely, antiseptics. A treatment originated in Germany in which mercury and iodine were the specific remedies. Excellent results were obtained from the use of these drugs, the temperature range and condition of the bowels being favorably affected.

I believe this good result was produced by the antiseptic action of the mercury and iodine. As I have said before, the primary lesion is in the intestinal canal. Here is where the typhoid germ is first deposited, and from the ulcerative process here developed is derived the secondary or pyæmic fever characteristic of typhoid. Now, the treatment which will act as directly as possible upon the ulcerating Peyer's patches, is as near an approach to anything "specific" as our present knowledge will permit.

It now becomes easy for me to say that my method of treatment, after supporting the patient with the properly applied milk diet, and stimulants when indicated, is by antiseptics. By this I mean that the alimentary canal should be kept in an aseptic condition from the mouth to the termination of the intestine. Of this, the attention to the mouth is not the least in importance. Many remedies are suitable, and this gateway to the alimentary canal should be securely guarded, so that no septic matter can find its way into the circulation through this channel.

That part of the intestinal tract beyond the ilio-cæcal valve can be reached by antiseptic enemata, which should be used at least twice a day.

Of the medicines to be administered internally, the mercurials are in the first rank. Tablet triturates of calomel, or bichloride, in very small doses, are the form used. The combination of carbolic acid with bismuth or iodine is valuable, especially where there are marked bowel symptoms. Pepsin is an excellent antiseptic, and, where the digestive powers are weak, aids in the elaboration of the food.

In speaking of the necessity for thoroughness in our treatment, I would say that our antiseptics should be continued until the dejections from the bowels are safely deposited where infection from them is impossible.

The results obtained by this method of treatment in a fairly large number of cases are these: the diarrhoea is much less, seldom requiring the use of opiates; the temperature range is not so high, and the tendency to complications is not so great. I do not believe any method of treatment now known will cut short the course of typhoid fever, but this method seems to me more rational than to savagely attack one of the many symptoms which are, in most cases, the necessary accompaniment of the disease.

In regard to treatment, then, I have only attempted to show that a conservative method, based upon what little real knowledge we have of the fever, is of more

value than the uncertain use of potent drugs which, while they for the time being seem to relieve one symptom may do the patient positive harm.

It may be said that I have simply done the work of a vandal, and have destroyed the idols which have been so long worshipped, having substituted but little in their place. But I firmly believe that, not only in this, but in all diseases, the time has come when thoughtful physicians say that we must use less, much less, medicine, and when administered, it should be with a definite purpose in view and in the smallest possible dose.

Although we are standing on the verge of marvelous revelations as to the cause of disease, and in a quarter of a century from now this labored essay would not be worthy of your consideration, yet, at the present time, our best results will be obtained by making use of the first steps which have been taken in our knowledge of this disease, and being extremely conservative in instituting uncertain and unscientific measures.

And I believe that the greatest step that has been taken within the last decade is in learning what not to do; in learning to place less confidence in the curative power of drugs, and watching more closely the indications of nature, standing ready to render all needed aid.

Our typhoid patients' surroundings should lack nothing to render their sanitary condition perfect, and the supporting and absolutely antiseptic treatment should be untiringly pursued.

I can close this paper with no better words than those of the immortal Jenner. He says: "My experience has impressed on me the conviction that the man will be the most successful in treating typhoid fever, who watches its progress, not only with the most skilled and intelligent, but also with most constant care, and giving *unceasing attention to little things*, and who, when prescribing an active remedy, weighs with the greatest accuracy the good intended to be effected against the evil the prescription may inflict, and then, if the possible evil be death, and the probable good short of the saving of life, holds his hand."

#### THE BACILLUS OF TYPHOID FEVER: ITS OCCURRENCE AND SIGNIFICANCE.<sup>1</sup>

BY JOHN A. JEFFRIES, M.D., OF BOSTON.

In 1882 Eberth announced that certain groups or colonies of short bacilli could be found in the Peyer's patches, lymph glands of the mesentery, spleen and other organs of those dead of typhoid fever. Meyer reported shortly after on the subject, and added much weight by showing that such groups of bacteria existed in nearly all cases of typhoid fever. This was before the general use of aniline dyes and solid culture media.

Next Gaffky showed that these groups of bacteria could be stained by long immersion of sections in solutions of methylene blue and washing in acidulated water. He also showed that the plant could easily be grown at room temperature, and that the cultures were quite different from any known at that time. The plant grew as a bacillus with rounded ends, was endowed with the power of motion, and apparently formed spores. Gelatine was never dissolved; the deeper parts of the shaft were beaded and slightly brown in color. The growth on potato was regarded

<sup>1</sup> Read before the Massachusetts Medical Society, June 9, 1891, and recommended for publication by the Society.

as a diagnostic character, the peculiarity being extensive growth as shown by the microscope, yet nothing to be seen by the naked eye except a slight shimmer or difference in texture when looked at in a favorable light.

Koch and others soon demonstrated not only that the bacillus occurred regularly in all active cases of typhoid, but also that it could not be found in those dead of other diseases. This put the subject in such a position that a few years ago one spoke of the typhoid bacillus as quite a settled matter. To-day we do not know half as much as then. The very individuality of the plant has been questioned. The difficulty has come from the discovery that a large number of bacteria exist which grow on potato just like the typhoid bacillus, and that some plants identical in all the culture characteristics given by Gaffkey are not so very rare, and occur in the stools of people with intestinal disease. As a result, the Eberth bacillus has been cultured in a great variety of ways, and subjected to a very close scrutiny, in the hope of discovering some character or group of characters by which it could be positively recognized. So far all efforts have been futile. If Babes is correct in his observations, there are a host of other bacteria, either closely allied species or varieties, which occur in man and chiefly in man with typhoid fever.

Even yet the difficulties of the case are only half related; the Eberth bacillus is a protean form, and varies much in its shape, form and manner of growth, with minute changes in its surroundings,—as temperature, degree of chemical reaction, and composition of the media. Therefore, to-day, to demonstrate that a bacillus is identical with Eberth's, it is necessary to compare it step by step, culture for culture, under precisely the same conditions with an undoubted culture, and to have derived the original supply from a case of typhoid.

The above conditions can be fulfilled in practically every case of typhoid fever which has died before the disease has passed off, and the original microscopic findings can be verified in the same way. Those conditions have never been fulfilled in a single case of other disease. We are, therefore, justified in claiming the existence of a peculiar bacillus or bacillus group in every case of typhoid. This is the ground on which the claim of the typhoid bacillus depends. It rests on the same evidence as the spirillum of relapsing fever, the plasmodium of malaria; both are always to be found in their respective diseases, never in health or other diseases. It is, therefore, clear that the typhoid bacillus and typhoid fever stand in some sort of causative relation; things which vary together, are connected causatively. From analogy and the improbability that the bacilli are the result of a secondary invasion, the bacillus is commonly accepted as the cause of the disease. No careful student claims this as proved, neither is the law of gravitation.

A few authors have attacked the integrity of the bacillus, and argued that typhoid fever is a condition, and the bacillus in reality a variety of species, as in the summer diarrhoea of infants. Others hold that the plant is simply a modification of a common denizen of the intestine. But epidemiology and clinical study point so clearly to a specific disease transmitted from case to case that I do not think these views need be entertained, at least until their supporters produce some substantial evidence.

The distribution of the plant in the body bears a close relation to the nature of the disease. First, it occurs in the substance of the swollen Peyer's patches, before these have sloughed, not simply in the mucosa, but in the round-cell aggregations. After the surface has become eroded and an ulcer is formed, the surface becomes literally coated with all sorts of bacteria, cocci, streptococci and bacilli; among the latter there is often a rather long bacillus, which Klebs at one time held to be the cause of the disease. Evidence, however, points to its being distinct from the typhoid bacillus. It only occurs on and in the surface of the erosions, not deep in the tissue. Nearly if not quite simultaneously with the appearance of the bacillus in the follicles, the lymphatics of the mesentery swell and show nests of the same bacillus. The nests contain from fifteen or twenty bacilli to hundreds, and form a mass varying in size from that of a nucleus to one very much larger. The centre is apt to appear almost homogeneous or finely granular; but the circumference clearly shows short, straight, irregular looking bacilli. The irregular appearance is due to parts of the bacilli staining less than the rest.

The spleen shows precisely the same state of affairs. According to the duration of the disease and other factors, the number of colonies vary greatly. In advanced cases, even two hundred sections may be examined before a colony is found. From this their prevalence runs up to as many as fifteen or twenty in a single section.

So far the colonies have been described as being in the tissue, between the cells, not as bearing any particular relation to the blood-vessels or other parts. To this the liver offers a contrast. Here the plant is apt to occur in the form of distinct thrombi, which have grown from minute emboli.

In the kidneys the colonies occur chiefly in the cortical portion; are often present, at times abundant, but apparently are not present with the same regularity as in the spleen.

Besides the above organs, the typhoid bacillus may be found in most any part of the body. Thus it is apt to occur in those cases of lobular pneumonia which so often complicate cases of typhoid. It has also been reported as existing in the meninges in cases of complicating meningitis, and in abscesses in such different parts of the body as the parotid glands and the tibiae. At times the bacillus is found alone, but mostly in company with some accepted pus-producing bacterium.

Numerous examinations of the blood in all stages of the disease have been made, and observers have reported positive results, especially from material procured by opening a rose spot. Others have failed. That the plant can occur in the blood, the emboli in the liver demonstrate; nevertheless, none of the observations are above question; many simply depend on the microscope and are absolutely worthless; others are supported by cultures, but in no cases have these been carried to that degree of fineness and accuracy necessary to establish even a probable diagnosis. Examination of the blood in doubtful cases for purposes of diagnosis is therefore a failure, and until our knowledge is greatly improved must remain so. Provided the typhoid bacillus was found, its positive recognition would require so much time that the practitioner would take but little interest in the result.

All the above remarks apply to the search for the bacillus in typhoid stools; it may be there or it may

not. Many claim to have found it, many have failed. The difficulties are enhanced by the enormous number of bacteria in faeces, and the occurrence of many typhoid-like bacteria in the intestines of typhoid patients. All sorts of ready methods of isolation have been recommended, but none have stood the test of time. The only feasible method is to make plate cultures from the stools and then search for the desired colonies. These have nothing characteristic about them, are variable, so that in searching for the typhoid bacillus plates of pure cultures of the typhoid plants must be made to serve as a control and comparison in each case. Even then the amount of error is large. Lately word has come that a regal road to the typhoid bacillus was found. All that is necessary is to use agar and put the plates in the thermostat and presto! the next day, thanks to the warmth, the typhoid (pathogenic) bacteria have developed finely, while the others, not liking heat, are retarded in development. Beautiful, but mistaken. All or nearly all the germs in the intestines thrive better at 98° than at 68°. There is nothing new about the method except the theory; by it we hasten development, and avoid liquefaction; on the other hand we lose the signs of the only absolute fixed character, non-liquefaction of gelatine, and run a considerable risk of killing the plants we want to study.

Considerable attention has been paid to the urine in cases of typhoid, and the weight of evidence seems to indicate that the bacillus is quite liable to appear in the urine when it contains albumen, that is, quite early in the course of the disease. As yet, however, the universal doubt which hangs over most everything relating to the typhoid bacillus weighs heavily. More evidence and closer work is needed before positive statements are justified. Reasoning from analogy, and the presence of the bacillus in the kidneys, their occurrence in the urine seems most probable.

The only other method of utilizing the bacillus for diagnostic purposes is that of tapping the spleen. This has been done on several occasions and the method is spoken of as a success. Probably none of us, however, would be willing to have our own spleens tapped for the sake of a diagnosis.

So far only the distribution of the bacillus in the body has been considered. There yet remain the relations of the plant to the cell changes and the result of animal inoculation. As to the latter the weight of evidence is that the plant is not pathogenic in any of our experiment animals, certainly is not capable of producing any disease similar to typhoid fever. The inoculation of large amounts kill a certain proportion of the smaller experiment animals, but this is evidently the result of various poisonous principles introduced, and not due to the multiplication of the bacillus in the body.

In man there are certain focal or localized cell changes, over and above the diffuse changes which are more or less characteristic of the disease. Thus we have certain small round-cell accumulations in the parenchyma of the various organs,—the so-called typhoid lymphomata, and also certain other patches characterized by the loss of the staining qualities of the cells, their partial atrophy and the splitting up of the nuclei into two or more strongly staining bodies. The final result is an almost homogeneous mass, in which close study may reveal the ghosts of the cells, through which are interspersed a number of deeply stained

highly refractive small bodies, the remains of the nuclei and some connective tissue cells. These two processes, though presenting similar optical appearances, and until recently grouped together, are in reality distinct. The first is a demonstration of life, the other of death. The same or a similar process is to be recognized in various parasitic diseases. At the present time no direct or rather topographical relation has been made out between either processes and the colonies of the typhoid bacillus. The tissue directly surrounding a colony may appear precisely like the body of the organ, or it may be altered in either of the above ways.

Again, either alteration may take place without any recognizable bacilli, so that allowing the pathogenic qualities of the plant we must attribute these changes to the general state of the body, as secondary manifestations rather than primary.

Wherever the bacillus is found it is not in the cells but between them. This shows very clearly about the borders of the colonies; at times a cell can be recognized in the thick of the bacteria. What becomes of the cells which occupied the places of the colonies I do not know; they must be either pushed to one side, digested, or simply obscured—very likely all three.

If the reported cases of the detection of the typhoid bacillus in stools and urine are correct—probably some are and some are not—we have an ocular demonstration of their mode of dispersion preparatory to reinfection. In my own mind there is no doubt but that the germ escapes from the body in one of, or both, these ways. With this point in mind, much work has been done calculated to show how long the typhoid bacillus can exist in dejecta, the ground, and water. Most experimenters have concluded that the time was rather short, the typhoid plant being crowded out by the other germs. This sort of work, however, is not productive of much good; our experiments will never equal those of nature. The answer to this problem is best found by a study of the numerous local epidemics of typhoid where the source is known, not in the bacteriological laboratory. Though no spore is produced, the time will be found quite long,—longer than might be expected of a plant which apparently is incapable of a prolonged independent existence.

What we want to know is how to sterilize the dejecta. The urine is easily cared for. A moderate amount of carbolic acid and time will do it. It is my custom in all cases of parasitic disease to have some antiseptic as carbolic acid always kept in the receptacle for the urine. When dissolved, corrosive sublimate is very effective, but where much albumen is present I have been afraid to rely upon it. The stools are not so easily dealt with; corrosive is not at all reliable. Carbolic acid in strong solution, so as to produce a three per cent. solution when intimately mixed with the dejecta, is safe. Just pouring some carbolic on and poking the mass with a stick will not suffice. Faeces are very difficult to sterilize. Some simple sort of oven or stove in which dejecta could be dried and burned is a great desideratum. Our large cities are supposed to see that the sewer waste is not dangerous; in smaller places out-door space for such an apparatus is most always at hand.

A word as to the examination of drinking-water. The epidemiologist attributed a prominent rôle in the spread of typhoid to water contaminated with dejecta long before the bacillus was found. Time has only strengthened this position. Of course, therefore,

many searches have been made for the bacillus in water—and what could be more natural than to find it? Yet Koch recently said that all reported discoveries of the typhoid bacillus in water must be accepted with reserve. It may have been found, but as yet the requisites of a demonstration have not been produced. Very much the same may be said of milk. Outbreaks of typhoid are occasionally apparently due to the consumption of milk contaminated with infected water.

In closing we have good reason to believe that Eberth's bacillus is a species and the cause of typhoid fever; that it escapes with the dejecta and after spending a variable amount of time at large is liable to gain entrance to another individual and reproduce the disease. Lastly that a large number of unjustified conclusions as to the finding of the bacillus in nature have been given to the profession under the guise of bacteriology. Some of the records may be correct, none are beyond doubt, and few are really worthy of consideration.

### MENTAL DISTURBANCES OF INFLUENZA.

BY J. B. AYER, M.D., OF BOSTON.

INFLUENZA, in my experience, became epidemic December 20, 1889, though I feel that I saw one case of influenza-pneumonia which was fatal, November 9, 1889.

At the end of seven weeks fewer patients were seen, but sporadic cases of influenza continued to appear throughout the year and up to midwinter, when the presence of the epidemic again became very marked, and has continued till the present time.

During the last four months of this "relapse" the pandemic character of the previous year was absent, the disease this time seeking out one neighborhood after another and exhausting its force more leisurely.

Dr. Rush's description of influenza as it appeared in Philadelphia in the autumn of 1789 (lasting six weeks), relapsing in April, 1790 (remaining till the early part of June), and ending with a mild relapse the following winter, is of value and of great interest now, as the epidemic which occurred just one century ago resembled ours with this exception, that the nervous and mental symptoms did not have the prominence in the affection which they hold to-day.

Probably, however, some recent authorities have overrated the importance of these symptoms. It does not seem to me possible to prove the claim that the disease is essentially an epidemic *Nervenkrankung*, observation showing that the influenza-germ seeks out the weak part of the human system, and that to-day the nervous system is obliged to bear the brunt of the attack more than it did a century ago, for the same reason that so many diseases have in that time tended to assume an asthenic, nervous type.

Dr. Clouston, in summing up an investigation of 110 cases of influenza among patients and attendants at the Royal Asylum, Morningside, concludes that "any sharp division of the symptom is artificial, and by no means accurate."

He found the patients complained as follows:

With severe muscular symptoms . . .	91.1 per cent.
With less pronounced symptoms . . .	7.7 per cent.
With almost no symptoms . . .	1.2 per cent.

I found this table very similar in results to an analysis made at the Home for Aged Colored Women in this city.

The 21 inmates (aged from sixty-one to ninety-three years), including the matron, escaped (with two exceptions) last year's epidemic, but were attacked this year—one on February 22d, the others between March 7th and 20th.

Thirteen inmates were severely attacked (one died).  
Five inmates were moderately ill.  
Three inmates were not confined to the bed.

The prominent symptoms, expressed concisely and in order of importance, were those of

Depression (C):	
Depression (feared insanity) . . . . .	1
Depression and irritability of temper . . . . .	1
Depression and cephalalgia . . . . .	4
Pain (A):	
Cephalalgia . . . . .	1
Cephalalgia and cough . . . . .	1
Cephalalgia and "grip-like" pain in chest, . . . . .	1
Pleurodynia and prostration . . . . .	1
Cough (A):	
Cough . . . . .	2
Cough and depression of spirits . . . . .	1
Cough, weakness and pleurodynia . . . . .	1
Vomiting and gastralgia . . . . .	1
"Dizzy head" and gastralgia . . . . .	1
Prostration and depression . . . . .	1
Prostration connected with pneumonia or pleurisy . . . . .	4

In two cases of partial dementia there was no increase of brain disturbance. One case died from pneumonia and co-existing phthisis.

Two months have elapsed, but, as yet, only two of the inmates are in as good general condition as before the attack. A diabetic patient, who has been growing infirm for many months, a fortnight after the disappearance of marked symptoms of influenza developed choreiform movements of left side, principally confined to left arm: symptoms now disappearing.<sup>2</sup>

I was forcibly struck with the fact that a large proportion (6 out of 21) of these patients remembered most vividly, and with the greatest dread, the symptom of mental depression in connection with their attack. Adding to this number those who complained principally of pain and prostration, we find that with many patients the nervous system bears the brunt of an attack of epidemic influenza.

I have seen several cases this season in practice, many more than last year, illustrating different degrees of mental disturbance in influenza, and I will refer to them briefly.

**Insanity requiring Hospital Treatment.**—I have met with one case of transitory mania where recovery occurred in four weeks. This was the third attack, but recovery was more rapid and satisfactory than before. The mental symptoms appeared early in the course of well-marked influenza, and were prominent on the seventh day. Influenza began suddenly at the supper-table with sharp pleurodynia.

Most hospital cases of influenza-insanity have the melancholic-hypochondriacal form, with favorable prognosis. The duration is often unusually short—even for post-febrile insanity.

**Psychoses not requiring Hospital Care.**—I attended a young lady who showed decided mental instability for twelve days, in connection with an influenza relapse where cephalalgia and fever were the prominent symp-

<sup>1</sup> See also paper read before the Medical Psychological Society, May 1, 1891.

<sup>2</sup> At the end of a few weeks the left-sided choreiform movements, which had subsided, again became marked and still continue. They are of organic cerebral origin undoubtedly.

toms. The patient wandered in mind, turned against her friends, was notional, fault-finding and pre-occupied during this time. For several days it was difficult to make a diagnosis and prognosis. Typhoid fever and kidney complications were eliminated, and symptoms were found to be clearly due to influenza and neurasthenia. Complete mental recovery at the end of a fortnight, physical condition improving steadily.

I have seen a case where there has been a marked change in disposition and temperament, together with a difficulty in articulation, following influenza characterized by severe cephalalgia and profuse nasal catarrh, which has been treated at home. Sufficient time has not elapsed to form a satisfactory judgment, but I feel that we are warranted in giving unusually hopeful prognoses in influenza cases.<sup>3</sup>

*Influenza-Meningitis with Coma.*—A patient, fifty-five years of age, contracted malaria in 1862, in army service. He was not in robust health when, on Christmas Day, 1889, he was prostrated by influenza. Cephalalgia was a prominent symptom, and he complained that his head did not feel right up to April 2d, when he was seized with severe headache, on the right side, which appeared at frequent intervals during a fortnight and was followed by convulsions, hemiplegia, and coma, causing death on the twenty-fourth day. There was no kidney trouble. Dr. Jelly, who saw the patient with me, agrees in attributing the symptoms to meningitis following influenza.

A case directly connected with influenza is that of Mrs. —, forty-four years of age. Two years ago a large abscess, which had slowly formed over the lower lumbar vertebra, was opened by Dr. M. H. Richardson, who on later occasions removed carious bone from the vertebra, a small sinus remaining.

Patient was in feeble health when attacked by influenza, the second day of the present month. The early symptoms were those of excruciating sciatic neuralgia, chilly sensations, and febrile disturbance (102°); a few days later there was severe cephalalgia. On the 13th there was severe prostration, but less pain and delirium, and I saw nothing about the symptoms which made me feel that there was immediate danger. On the 14th she had a sharp chill, with severe cephalalgia and general pain, and also hallucinations of sight and hearing. There was profuse, clammy perspiration following the severe headaches. She became deaf and inattentive. There were frequent chills followed by fever. On the 15th there was a state of partial stupor. Head was very hot, cephalalgia continuing till stupor was more marked. After the morning of the 17th she could not be aroused. Irregular respiration was a marked symptom, and paralysis of left arm was marked. Examination of the urine showed that the symptoms were not of uræmic character. She died on the 18th, sixteen days after first symptom of influenza.

The Reports of the New York State Board of Health show a large increase of deaths from all forms of nervous disease monthly (when compared with previous years) since the first appearance of the epidemic.

The Mortality-rates of the City of Boston do not confirm the view that fatal cases from mental and nervous disease have increased during the past sixteen months, excepting that cases of apoplexy and suicide have been more numerous than usual.

<sup>3</sup> The patient, however, died three months later suddenly from cerebral apoplexy.

*Delirium during the Attack of Influenza* was quite common, and was generally of an asthenic character and transient. The patients could be easily recalled from wandering. Syncope occurring at the outset of an attack did not seem to be an unfavorable symptom.

*In Pneumonic Complications* delirium was often protracted, and of longer duration than is usually seen in ordinary pneumonia.

*Delirium (with Gastric Symptoms) preceding the Febrile Symptoms of Influenza.*—A case illustrating the fact that the diagnosis may remain in doubt for several days, is that of a boy, nine and one-half years of age, who was prostrated on the 4th instant with obstinate bilious vomiting. He was a precocious child, and had a large head, but never complained of any troubles except bilious attacks and constipation. Following two days of persistent vomiting, he became mildly delirious. He complained of pain extending from the umbilicus to the ensiform cartilage, and worried about himself, especially about his heart, maintaining that he felt that organ "hanging down," and beating too rapidly.

Frequent vomiting, local hyperæsthenia, and occasional delirium continued till the 10th instant, before there was any rise of temperature or any other proof of influenza. From the 10th to 13th the temperature fluctuated between 100° and 102°; the delirium was more constant, but was of a quiet type. Occasionally he had hallucinations of sight, but would smile when he was corrected regarding his fancies, readily recognizing his mistakes. He worried a good deal about heart disease up to the 14th instant, but has since been clear in mind, and is now out of doors.

*Influenza causing Neurasthenia and Apprehensiveness.*—Our local experience has borne out the testimony of Dr. Clouston, that "the year 1890 has been depressing in its conditions to the nervous system, the epidemic of the preceding winter having left the nerves and spirits of the people in a worse state than it found them."

Rheumatic and dyspeptic complaints, with prolonged depression of spirits, have not been uncommon. I have in mind a case of rheumatism where for more than a year the feeling of apprehensiveness has been out of all proportion to the importance of the rheumatic symptoms. I recall two cases, both elderly people, where the persistency of dyspeptic symptoms with hypochondria made me consider seriously the question of serious gastric disorder, but where epidemic influenza was to blame for the obstinacy of the disorder.

The neurasthenics have been the greatest mental sufferers of the epidemic. The feeling of apprehension has not been confined to adults, as was illustrated by the case of the boy who was worried about his heart. During the past year I had considerable difficulty in convincing a girl, ten years of age, that she did not have heart disease. Worry of this nature in young children I have never previously encountered.

Influenza modifies nearly all diseases at the present time, and its influence, especially upon the nervous system, must be considered in every case. All who have attempted the study of the epidemic will agree with the statement in the last number of the *British Medical Journal*, "In spite of considerable increase in our knowledge of the behavior of epidemic influenza gathered during the past year, much still remains mysterious."

Other cases come to mind of nervous disturbance and

depression, which I firmly believe (but perhaps cannot prove) to have an influenzal origin. There come notably under this head cases of slight injury, where the symptoms are strangely protracted, and the prostration excessive, which may be due, in my opinion, to the co-existence of influenza.

## Clinical Department.

### DIPSOMANIA.

BY LUCIUS W. BAKER, M.D.

*Superintendent of Worcester Sanatorium for Nervous Invalids, Holdenville, Mass.*

Not long since I had under my care a young gentleman, twenty-six years of age, belonging to a refined, intelligent family. His father was a moderate drinker, and died in middle life of Bright's disease, bequeathing to his child an unstable, nervous organism, which predisposed its unfortunate owner to some form of mental or nervous disaster. The earlier history of the patient is one of alcoholic excess, later occurring periodically, when the desire for stimulants would be irresistible. He would pawn his clothes or do anything to satisfy the craze for intoxication.

During these periods, if denied alcohol, there would be complete loss of appetite and inability to sleep; his eyes would become bloodshot; his gait staggering; his conversation would be voluble, silly, and incoherent, and delusions would often be present. In short, he would at times present all the phenomena of intoxication without having, to my certain knowledge, partaken of a single drop of alcohol.

The symptoms presented by this patient are clearly indicative of a profound disturbance of the nervous system, which manifests itself by an intense periodical craving for intoxication. They are similar in their origin to those morbid impulses to commit theft, set fire to buildings, etc., which are occasionally met with, and like these are due either to a loss of controlling power in the higher cerebral centres, or to an excessive morbid accumulation of nervous energy which exceeds the normal controlling power of the individual.

The distinguishing characteristic of these disorders is a morbid and irresistible desire to perform certain acts without the presence of any positive delusions; while varying in their manifestations, they are generally periodical in their occurrence, and are dependent upon an unstable condition of the brain cells, which may be acquired but is generally inherited.

Especially is this the case in that intense periodical craze for intoxication known as dipsomania, which Dr. Spitzka has defined as "A form of periodical insanity manifesting itself in a blind craving for stimulant and narcotic beverages." In nearly every case of dipsomania careful study will detect some impairment of brain or nerve tissue, some imperfection of cerebral element, which in the majority of instances antedates the desire for alcohol.

During the intervals between the drink paroxysm the dipsomaniac has usually no desire for alcohol, indeed it may be actually repulsive to him. He may then sign the pledge, and make most strenuous efforts to reform; but during the attack all his powers of control, all his manhood and self-respect are overwhelmed by the craving of the nerve centres for intoxication. Nothing but absolute physical restraint will prevent

excessive indulgence. For the time being, the man's whole moral tone is changed, and he will often seek the society of the low and degraded with whom he would never dream of associating under any other circumstances.

These changes of character, these overpowering impulses for intoxication, with intervals of total abstinence, are symptomatic of an intense disturbance of brain function, and characteristic of dipsomania.

The dipsomaniac is the victim of a distinct neurosis, which is very closely allied to insanity. He should not be confounded with the confirmed inebriate in whom the desire for alcohol is nearly always present. The latter often indulges to excess, and may become intoxicated, but he does not present the characteristics of dipsomania.

It is true that a genuine case of dipsomania is seldom met with in contrast with the number of confirmed inebriates, but it is none the less important that the characters of the disease should be promptly recognized and intelligently treated. During a paroxysm of dipsomania the individual is really insane and irresponsible for his acts, as much so as a case of acute mania. To regard him as a moral delinquent, and subject him to moral means alone for his relief is unscientific, and reminds one of the time when insanity was regarded as an indwelling evil spirit, to be driven out by chains and the lash.

We may as well expect the suicidal maniac to observe a promise not to take his own life as to expect a man to voluntarily refrain from the use of alcohol during an attack of dipsomania. Both are diseased, both need restraint and intelligent medical aid.

The first step to be taken in dealing with the dipsomaniac is a recognition of his diseased condition; when this is acknowledged, dipsomania passes from the domain of morality which it has held so long, and becomes a proper subject for the consideration of the physician. The dipsomaniac, unable to resist the terrible drink craving, will then no longer be regarded as a moral delinquent, but as a sick man needing special medical care. This, as a rule, can be best obtained in institutions devoted more especially to this class of cases, and in charge of physicians who have made special study of the various forms of inebriety.

## Reports of Societies.

### MEDICO-PSYCHOLOGICAL SOCIETY.

MEETING of May 21, 1891.

DR. JAMES B. AYER read a paper on

#### MENTAL DISTURBANCES OF INFLUENZA.<sup>1</sup>

DR. FISHER said that there were many cases of influenza among the staff and employees last year while the patients, for the most part, escaped. This year some of the patients had been affected. He spoke of a woman of sixty, nervous and with uterine troubles. At the climacteric she had been haunted with the idea of pregnancy, which constantly recurred associated with excessive sexual feeling. The idea of being alone with a man would suggest pregnancy. She recovered and remained well for ten years. After the influenza, she had insistent ideas — not of pregnancy, but chang-

<sup>1</sup> See page 291 of the Journal.

ing. One idea was that she saw snakes in the grass, and the idea of verdure would cause a shock, creeping sensations and erotic feelings. The same feelings occurred if she saw a hat trimmed with green. She probably had no hallucination of sight or hearing, and eventually recovered.

DR. BAKER spoke of a case of melancholia with agitation which followed an attack of gripe.

DR. WEBBER thought that cases of gripe would tend to produce melancholia when there was sleeplessness, and where the digestive organs were affected. He spoke of one of his patients who could only eat in the morning, and had nausea and vomiting in the afternoon, associated with sleeplessness and depression. One patient had depression after three nights of only two hours of sleep, but recovered her spirits after a good night. One patient, during an attack of gripe, had a curious state of mental neurasthenia; was fault-finding and complaining. When she recovered, she recognized this change of character. He had only observed depression, but could understand how it might proceed to melancholia.

DR. KNAPP had seen but one case of insanity from influenza. There seemed to be a lowering of the plan of nervous energy, increased neurasthenic symptoms, and mental depression.

DR. LANE had seen more cases of gripe among employees than patients. It could not be strange to get mental symptoms among the insane. In one demented there was prolonged delirium during the gripe, with lowered tone of the whole system. Physical recovery was followed by mental improvement.

One of his friends had been left in an emotional state so that the ringing of the door-bell would move her to tears.

DR. HOLT spoke of two patients actively suicidal who were admitted to the hospital. In both the gripe was supposed to be the exciting cause of their mental sickness. Both recovered.

#### NEW YORK STATE MEDICAL ASSOCIATION. FIFTH DISTRICT BRANCH.

(Concluded from No. 11, page 276.)

SEVENTH annual meeting, held in Brooklyn, May 26, 1891, the President, STEPHEN SMITH, M.D., in the chair.

#### AFTERNOON SESSION.

THE PRESIDENT delivered his address, his subject being

#### OPiates IN THE TREATMENT OF ACUTE PERITONITIS.

He commenced by quoting from Prof. Alonzo Clark's account of the outbreak of puerperal fever at Bellevue Hospital, in the year 1851, given in the article on Peritonitis in his "System of Practical Medicine." In speaking of the latter, Dr. Clark says: "In three or four days seven cases were sent to me from the lying-in wards. One was returned for error in diagnosis, and six put under treatment. Having found that prudence was so much more conspicuous in my house-physician than courage, another house-officer, who combined them both, was selected to be in almost constant attendance. The instructions were in these words: 'I want you to narcotize those women within an inch of their lives.' He did it, and saved every

one of them. This gentleman is now known over the whole land as a learned and distinguished surgeon. I feel called upon to give his name in this connection, that he may be a witness to the facts I state, and for the admiration with which his nerve and prudence impressed me."

Dr. Smith said that notwithstanding this assertion, Professor Clark failed to give the name of the surgeon referred to, but as he himself was then a resident in Bellevue Hospital, and had charge of the six cases mentioned, he assumed that he was the person meant, and would take this occasion to witness to the facts thus recorded. He then gave a very interesting account of the slow elevation of Bellevue from a prison and almshouse into a hospital purpose. The buildings, erected in the early part of the century, and built chiefly on ground reclaimed from the river, were very massive in construction, but without under-drainage or sewerage. All forms of contagious and infectious diseases were received into its crowded and ill-ventilated wards, and at various times yellow fever, typhus and typhoid fevers, small-pox and cholera were the prevailing diseases of its inmates. In 1846-7 there came a complete change in the administration of the institution by the selection of a competent medical board and the final retirement of the resident physician, whose appointment had been purely political, and who had been the sole authority in managing its general and medical affairs. At this latter date Bellevue, as an organized hospital, had its origin. There was, however, comparatively little improvement in the sanitary condition of the hospital buildings for many years. Gradually, better ventilation was secured, and the general cleanliness of the wards and beds was improved.

Having given a more particular account of the lying-in wards, he said that the mortality from puerperal fever was appalling. Of 21 cases reported by Dr. Vaché, the resident physician in 1840, 19, or nearly 90 per cent. proved fatal; nor was this death-rate unusual at that period. He gave a *résumé* of the records of the autopsies in these 19 cases, made by Professor Clark, and said that these records were more or less accurately repeated on every recurrence of puerperal fever at Bellevue between the years 1840 and 1851. The treatment was so mixed that it was difficult to draw any conclusions as to the efficiency, or rather inefficiency, of any one remedy. Still, it was noticeable, that purgatives were actively employed in 17 of the 21 cases, and that in 5 cases the purgative was salts. In the other cases, calomel and turpentine, two approved antiseptic remedies, were administered freely. Purgatives in the form of opium and Dover's powder were given in most cases, but in small and occasional quantities. Professor Clark truly said: "Up to the time when the opium treatment was adopted peritonitis was a fearful word; a large proportion of those attacked by it died of it."

Dr. Smith described in detail the treatment of the six cases placed under his charge by Professor Clark, who gave the most particular directions as to their care. He was required to see the patients every hour, and in regard to the opium he was not to be governed at all by the amount administered, but by the effects produced. He was to closely watch the pulse and respiration, and while the respirations might fall to 12 per minute they were not to be allowed to go below that figure. At the outset, each patient received one grain

of opium every hour, for three doses. No effect being perceptible, the dose was increased to two grains every hour, and continued for three doses. Failing with this dosage, the opium was increased to three grains every hour. In four cases this amount of opium had the desired effect, and it was continued in that amount. In the remaining cases it had to be increased to four grains every hour. One of the remaining cases yielded to this amount, and the opium was continued at that rate. The other, or sixth, case was much more obstinate, and the opium was steadily increased until the dose reached twelve grains every hour. This case proved an anomaly in tolerance of opiates. During twelve days the patient took the equivalent of 1,950 grains of opium, and yet at no time was she so narcotized that she would not awaken when any one placed his hand on her wrist.

The recovery of these six consecutive cases of puerperal fever naturally produced a profound impression. As the cases were typical of those ordinarily occurring in this hospital, and as opiates were the sole remedies used in their treatment, it was apparent that a new era in the treatment of that scourge had begun.

From this time forward opium continued for twenty years to be the chief remedy employed in peritonitis in Bellevue Hospital, and with satisfactory results. Opium in peritonitis came into use generally in the city, and Professor Clark stated that in private practice the drug had been perhaps more curative than in the hospital. With the introduction of the opium treatment the mortality from puerperal peritonitis in Bellevue was reduced certainly fifty per cent.; and this fact led inevitably to the conclusion that this treatment has a place in the therapeutics of that affection of no small importance. Precisely what that position was, it was perhaps impossible now to state. Professor Clark regarded opium as valuable chiefly in simple, uncomplicated peritonitis; and yet the clinical features of the six puerperal cases which occurred resembled in all their essential peculiarities the fatal cases reported by Viehe, in many of which the inflammation of the uterus and its appendages was the dominant lesion.

Happily, in these latter days, Dr. Smith went on to say, antisepticism had greatly diminished the frequency of this formidable disease, especially the puerperal form, and in the meantime the remedial measures had been greatly increased. Modern research had shown that peritonitis not due to putrefactive organisms was local, while peritonitis produced by such pathogenic microbes as *staphylococcus aureus* was rapidly fatal by general infection. One of the most important results of recent investigations was the differentiation of the types of peritonitis caused by various agencies; and as there were many types of this affection, having their causation in various conditions (some being of microbic, and others of non-microbic origin), it was as yet by no means certain where the line was to be drawn between the medical and surgical treatment. It was probable that the physician and surgeon would more wisely treat the multifarious types of peritonitis by acting in concert, and discretely employing the measures which each possessed according as they might jointly interpret the indications.

Whatever might be the possibilities of the art of surgery in the treatment of peritonitis, the question might be pertinently asked, Has any remedy, or combination of remedies, in the hands of the physician, given result equal to, or better, than opium in a series of

cases similar to those recorded in this paper? And if it be true that by employing opium, as recommended by Professor Clark, more than fifty per cent. of cases of peritonitis, as met with in practice, can be saved, should not this method of treatment be at once adopted in all cases, and the resources of surgery be applied where the manifestations of the disease indicate the necessity of its additional remedial measures?

DR. A. L. CARROLL remarked that it was noticeable that the advocacy of saline cathartics in peritonitis came, as a rule, from the abdominal surgeons, such as Lawson Tait, for instance. It seemed to him, however, that the peritonitis sometimes following operations was very different from the septic peritonitis of puerperal fever, it almost always came back again. In puerperal peritonitis, which was at first visceral, and afterwards extended to the parietes, opium was in his opinion strongly indicated, as it quieted reflex irritation and prevented the rubbing upon each other of the inflamed surfaces. Here he would give an occasional mild cathartic in connection with the opium. The enormous distention of the abdomen seen in some cases of peritonitis, indicated, he thought, an effort to get rid of something; and in such cases good results have been obtained from the moderate use of purgatives.

DR. J. W. S. GOULEY said that he was able to add two cases of recovery from puerperal peritonitis under Dr. Clark's treatment at Bellevue Hospital, to those which had been given in the paper. They occurred in the year 1853, when he was an *interne* at the hospital, and he had charge of them under Dr. Clark. The opium was pushed to such an extent in these cases that the respiration was kept down to between six and nine a minute.

DR. T. H. MANLEY referred to the discussion on the management of peritonitis in the Surgical Section of the American Medical Association at the Newport meeting, and spoke of the extreme opposition with which everything in the way of palliative treatment was met. His own experience, however, had led him to regard the opening of the peritoneal cavity as a more serious matter than many seemed to consider it; and he believed that in the next ten years there would be fewer laparotomies performed for the relief of inflammatory conditions than had been the case during the past ten years.

DR. WM. MCCOLLOM spoke of his early experiences in Vermont, where he said there used to be a good many cases of acute peritonitis which were not of puerperal or septic origin, but belonged to the variety known as idiopathic and were due to the same influences which produced acute pleurisy, for instance, such as cold, exposure, etc. When he was a student the physicians there used to begin the treatment with bleeding, and then followed this up with cathartics, as they had an idea that peritonitis commenced with some obstruction of the bowels. They first gave calomel and jalap, and if this medication failed, resorted to croton oil. The result was that the patient was agonized with pain and in a day or two died. Soon after he himself began to practice, he heard of Dr. Clark's opium treatment, and he resolved to try it at the earliest opportunity that presented itself. The first case that he met with was that of a young girl, and he gave her as much as fifty grains in one day; remaining in close attendance and watching the effects of the drug. The good result in this case induced him

to pursue the same treatment in others, and he found that he saved almost all of his peritonitis cases. He had continued this practice for the past thirty-eight years, and was firmly convinced of the superiority of the opium treatment.

The PRESIDENT, in closing the discussion, said that he did not wish to be misunderstood as regards the paper he had read. Its object was merely to give the history of the introduction of the treatment of peritonitis by opium into Bellevue Hospital; and not to advocate the claims of this plan of treatment in general.

Dr. H. W. MITCHELL read a paper on

PRACTICAL RESULTS OF THE OPERATION FOR LACERATED CERVIX UTERI.

The operation of trachelorrhaphy, he said, aimed primarily to restore the contour of the cervix to its normal condition, and secondarily—a much more important object—to insure its future usefulness. A patient who had undergone this operation should be so far restored to her original and normal condition, as to enable her to assume future pregnancies and to pass through parturition safely, successfully, and without a repetition of the former lesion. With proper attention to details in performing the operation, and in the subsequent care of the case, healing by primary union was almost certain. In a record of two hundred cases Dr. Mitchell said that only two healed by granulation; the others all healing by primary union.

Of these two hundred cases, he had been able to follow up twenty-one cases where subsequent confinements had taken place; and of these twenty-one cases eight had had more than one subsequent confinement. These twenty-one cases had been attended personally by himself at the time of their confinement, and he proceeded to give a *résumé* of them. All were of a severe form of laceration, and in some there was laceration of the perinæum in addition. Relaceration of the cervix during subsequent confinements occurred in only two instances, and in both cases it was so very slight as not to impair the usefulness of the cervix or render a second operation necessary. In conclusion, he said that if we might judge by these twenty-one cases (which were all that he had had the opportunity to observe in which he was familiar with all the details), we could say with truth that the operation was a proper and successful one, and accomplished the following results:

(1) Diminish the pain and irritation following upon such a distressing lesion.

(2) Relieve the sense of bearing down.

(3) Cure the exhausting leucorrhœal discharge, restore the parts to their normal and healthful condition, and, above all, restore the natural functions of the cervix so that future pregnancies and labors may take place in a natural and healthy manner, and without subjecting the patient again to the train of distressing and painful symptoms calling for the operation of trachelorrhaphy.

Dr. T. J. MCGILLICUDDY read a paper on

OBJECTIONS TO ORDINARY AXIS-TRACTION INSTRUMENTS; ALSO, THE ADVANTAGES OF THE ANTI-CRANIOTOMY FORCEPS OVER VERSION IN PELVIC DEFORMITIES.

While the correctness of the principle of axis traction, he said, was conceded by all, there were still many fallacious ideas in connection with its produc-

tion. Among the most common of these were the following: (1) That it is necessary to have rods attached to the blades by a movable joint; (2) that the traction, whether with tapes or rods, must in no way be connected with the handles, which ought to move freely in all directions; and (3) that rotation and flexion of the head can take place only when Tarnier's instrument, or one similar to it, is used. These ideas, he believed, were detrimental to proper axis traction, as it was well known that in the skilful use of the forceps we should frequently unlock the blades that the head might undergo rotation and accommodate itself to the pelvic canal; and it was also a fact that Tarnier's instrument, when clasped to the infant's head, interferes with rotation.

Dr. McGillicuddy then exhibited the axis-traction forceps devised by him, which were first described in the *American Journal of Obstetrics* for December, 1889, and said that with this instrument we could make ideal axis traction during the entire passage of the fetal head with remarkable ease and safety. With it, rotation in the posterior positions could be readily made by means of the adjunct handles, if it were thought best to use the forceps for that purpose. It was easy of application, and in its dual character it had all the advantages of axis traction and the ordinary forceps, and saved the expense of buying two instruments.

Passing on to the second part of the paper, he said that the forceps have an undoubted place as a compressor in certain cases. We were at all times to follow nature's guidance; it was well known how frequently the infant's head became elongated and otherwise distorted by pressure in its passage through the pelvis, yet without damage to the cranial contents. Therefore, as some compression of the head of the child was compatible with its safety, and as there was no modern instrument, so far as he was aware, that stood between the ordinary forceps and the cephalotrite or cranioclast, he thought there could be no doubt of the utility of the forceps which he now presented, which was intended to be used as a substitute for craniotomy or version in cases of pelvic contraction of moderate degree or where the ordinary forceps was unsuccessful. It was an efficient tractor, and at the same time it made moderate transient compression of the flexible upper portion of the infantile cranium, while it did not press too strongly on the child's neck with its tips. Thus, it gave the child a chance for its life, while it minimized the risk to the mother. It was safer for the mother than craniotomy, and it was also quicker and better than turning. He then proceeded to give in detail Simpson's arguments in favor of version in contracted pelvis, and claimed that in every particular his anti-craniotomy forceps had greater, or at least equal, advantages. This instrument, he said in conclusion, was not a cephalotrite or cranioclast, but a conservative, life-saving forceps, to be used in cases of considerable deformity. No woman should be delivered except by axis traction, and with its axis-traction handles one could determine the exact amount of resistance and the proper amount of force to use, and readily use it. With this forceps we pulled directly in the axis of the brain. The conclusion at which he said he had arrived was, that, when this instrument cannot deliver a living child, there is no alternative but Cæsarian section, as craniotomy in the living fetus is not justifiable.

DR. R. H. SAYRE read a paper on a case of

OBSTINATE NEURALGIA FOLLOWING FRACTURE RELIEVED BY OPERATION.

The patient was a young man who, between the age of five and fifteen fractured the right femur in its upper third. After the third fracture the bones (in which there had previously been straight union) united at an angle, causing a very marked curving of the thigh and between two and three inches of shortening. From this time he suffered constantly from neuralgia of the limb, which was greatly aggravated by motion or by handling of the parts, and which gradually became so intense that he was obliged to keep himself under the influence of morphia. The pain was most severe at the point of greatest deformity, which was just in the line of the external cutaneous nerve. All remedies having failed in curing the trouble, and several surgeons having concurred in the opinion that there was a large exostosis pressing on the nerve, Dr. Sayre operated on June 10, 1888, under antiseptic precautions. He found, to his surprise, that part of the vastus externus muscle was so twisted on itself as to turn at right angles to the long axis of the femur, and that there was no exostosis present, with the exception of a most minute point, which could scarcely be considered abnormal, but which he nevertheless removed. He then passed his finger completely around the femur, stripping up the muscle for an extent of two or more inches, but failed to find any sharp projection or anything else to account for the pain. Contrary to his expectations, under those circumstances, he found that the patient was completely cured by the operation, of the neuralgia from which he had then been suffering for six years, and which had resisted all kinds of treatment. On January 29, 1891, Dr. Sayre received a letter from the patient in which he stated that he still continued entirely free from pain.

One of the points of interest in this case, to which attention was called, was the simulation of an exostosis by what was presumably a tense fibre of the fascia lata, which had become so much bound down as to press on the muscles of the thigh, and which, by girdling them, apparently caused the pain. He said he did not clearly understand how to account for the abolition of the pain. He did not consider the point of bone he removed large enough to have caused the trouble, and he did not think that when he passed his finger around the femur he tore loose any nerve fibres from the cicatrix. The explanation, he suspected, was to be found in the relief of tension given by splitting up the fascia lata, which certainly bound the muscles very tightly. The length of time that had elapsed since the operation, nearly three years, he thought was sufficient guarantee that the cure would be permanent, especially as the patient had been addicted to the opium habit; and such habits were proverbially hard to cure of neuralgias, since the latter offered so good an excuse for returning to their old habits.

THE QUALIFICATIONS OF A PHYSICIAN IN OLDEN TIMES. A statute of Henry VII. ordains that the practice of the healing art shall be limited to those person that be profound, sad, and discreet, grandly learned, and deeply studied in physic.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 17, 1891.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,  
283 WASHINGTON STREET, BOSTON, MASS.

AN ATTEMPT AT A METHODOLOGICAL TREATMENT OF GONORRHOEA IN THE MALE.

In the *Annales des Maladies des Organes Genito Urinaires*, for June, 1891, is an article on the rational treatment of acute gonorrhoea in the male, by Dr. Paul Thiéry, which has been the subject of favorable comments by Dr. E. Desnos in the last number of the *Bulletin de Thérapeutique*.

Dr. Thiéry starts with the sufficiently obvious statement that all cases of blennorrhagia are not amenable to the same treatment. The treatment should vary with each period of the disease, and often with each patient.

A blennorrhagia may be said to be *regular* when it presents itself under the following circumstances: Supervening in a subject for the first time or reappearing after a first attack which has been thoroughly cured, leaving no trace; pursuing from the start an acute (not torpid) course; coming on in a person previously healthy and robust; lastly, has not yet been treated. In these conditions we can recognize five periods: a first period from the first to the third day — slight heat, appearance of a slight mucous discharge; second period from the third to the tenth or fifteenth day — heat, sharp pain, abundant discharge; third period from the fifteenth to the thirtieth day (may end in complete recovery at the end of two or three weeks), — pain abating, discharge sero-purulent, then sero-mucous; fourth period, of chronicity relatively recent — discharge sero-purulent, relapses readily happening; fifth period, blennorrhoea inveterate, discharge almost nil, dating from several years.

If each period demands special therapeutic measures, this is not the case with the general treatment, with the hygiene of the patient, which must be the same in nearly all cases, at least during the three first periods. This consists in the interdiction of all alcoholic stimulants, of all fatiguing exercises, and the sum of precautions universally known and recommended. Nevertheless, as far as coitus is concerned, Thiéry formally prohibits this only during the first

periods; he is disposed to allow it as soon as the discharge has nearly ceased, with the intent of diminishing the erections and nocturnal pollutions which too prolonged continence renders frequent. This, however, he concedes with a great deal of reservation, and not without suitable advice as to protection against contagion.

During the first period, the *abortive treatment* may be attempted on the first, second or third day after the inception of the disease; this period having elapsed, the chances of success are almost nil. This is Dr. Thière's method: The patient having urinated is placed in a recumbent posture; the ureter is washed with a boric solution and rendered insensible by cocaine. An instillator-bougie is carried down to the cul-de-sac of the bulb; several drops of a tolerably strong solution of nitrate of silver (one-fortieth to one-thirtieth) are injected; then the instrument is withdrawn, and during the act of withdrawing, the surgeon presses down the piston of the syringe so as to bathe the whole extent of the canal to the meatus. The reaction is severe, and one injection often suffices; sometimes it may be proper to make a new injection several hours afterwards with a somewhat weaker solution.

This treatment is, in fact, very painful, and the more so as the entire canal is brought under the influence of the caustic. Dr. Desnos, in his criticism, thinks it useless to apply the caustic to so large an extent of surface, and if he sees the patient at any time during the first two days, he contents himself with passing a No. 8 or No. 10 instillator-bougie to the posterior extremity of the fossa navicularis, convinced that almost never at this period has the inflammation passed this limit. He very slowly injects a small quantity of a solution of argent. nit., one to fifty, taking pains to have the liquid flow back immediately by the meatus; only twelve to fifteen cubic centimetres are thus injected; this irrigation lasts seven to eight minutes. The reaction is always intense, and it would indeed be very heroic treatment to repeat the injection at the end of several hours.

This method ordinarily succeeds when it is applied at the opportune moment. When it fails, or when the patient presents himself at the clinic after the third day, another mode of treatment must be adopted. Thière employs one of the following methods. The first is the "classic" treatment which every one knows: at the onset, bicarbonate of soda and baths; the first period passed, opiates and balsams. The other treatment to which Thière accords the preference has injections of iodoform for its basis. This is his formula:

R Iodoform, pure and in very fine powder (porphyrised), 1 part.  
Oil of sweet almonds (or glycerine) . . . . . 6 parts. M.

The physician cannot be expected to make the injections for his patients, but he ought to give them special instructions and show them how to make the first, for the *modus faciendi* has here a capital importance.

The injection is made immediately after micturition; the patient lying on his back injects slowly under a

gradually increasing pressure eight grammes (or about two fluid drachms) of liquid till he begins to feel the need to urinate; the syringe is then withdrawn and the finger applied over the meatus, while the injection is kept up from ten to twenty minutes. The injections are continued till there is a complete cessation of the discharge; this generally comes about in a very short time.

Desnos in his Bulletin review article approves of this method of treatment, but does not think it necessary to inject quite so large a quantity of liquid, unless indeed there are precise signs to indicate that the blennorrhagia has invaded the posterior urethra. Moreover, the odor of iodoform which clings to patients who have once undergone this treatment is to many a serious objection. Iodol, which is almost inodorous, may be substituted for iodoform, but its antiseptic power is less, and the results are less satisfactory.

When the iodoform injections have failed to produce a complete arrest of the discharge, or when, for any other reason, the disease has reached the third period, Dr. Thière suspends all local treatment as well as the employment of emollients, and prescribes only balsamics (copaiba, santal, etc.) for a time, which is always rather long.

The discharge at last disappears, or, in the immense majority of cases, becomes quite insignificant. This trifling oozing ought, none the less, to be the object of solicitous attention, for it is the signal that the disease is passing to the chronic stage; here the resort should be to the weak injections of nitrate of silver so much in favor among genito-urinary surgeons at the present day.

Lastly, these injections (or as the French writers prefer to call them, *installations*) of nitrate of silver constitute the principal feature of the local treatment of the fifth period; the strength of the solutions varies according to circumstances. It is hardly necessary to add that during all the periods of treatment, a severe dietetic regimen should be followed; and that the same remedies should be continued for several weeks after the patient seems to be cured. Convalescences from blennorrhagia are always sufficiently tedious; this is due perhaps to the fact that the advice and prescriptions of the physician are not carried out with sufficient rigor and regularity.

#### CROTON WATER-SUPPLY.

THE chief engineer of the Croton Aqueduct has made a report in regard to the alleged pollution of the water-supply, and its moderation and carefulness of statement ought to have a reassuring effect upon those who are apt to be affected by the periodical scare in regard to the condition of Croton water. At the same time the fact is distinctly recognized in it that the greatest danger to the quality of the supply arises from the flow into the tributary streams of liquids charged with refuse matters from the most thickly populated portions of the water-shed. At the present time, while

the condition of the water is by no means as satisfactory as it ought to be, and as, by the adoption of certain precautions, it is believed, from the natural purity of the sources, that it can be made, there is no ground for serious apprehensions in regard to the matter. The rapidly growing centres of population along the Croton water-shed, however, constitute a constantly increasing menace to the public health, and the adoption of suitable legislation to protect the purity of the sources would seem to be imperatively demanded in the near future. As to the contamination of the water in certain reservoirs to which attention has been called, the presence of a considerable amount of organic matter is held by the chief engineer, in his report, to be a phenomenon of uniform occurrence in all newly flooded reservoirs. However carefully the ground may be cleaned before flooding, there will be vegetation left whose decay will liberate sulphuretted hydrogen. Exposure to the air rids the water of the noxious gas, and the organic matter which may be held in suspension is not dangerous.

#### MEDICAL NOTES.

A BACTERIOLOGICAL INSTITUTE IN ST. PETERSBURG is to be established by command of the Czar, who has given a large sum for the purpose.

THE HOLIDAYS AT GERMAN UNIVERSITIES. — The new Cultus Minister, Graf von Zedlitz-Trützschler, has been directing his attention to the holidays at the high schools and universities and thinks they are unnecessarily long. He has, therefore, issued directions that for the future the summer vacation instead of lasting nominally now from August 15th to October 15th, but really extending to November 1st, shall be from August 1st to September 30th, and that the lectures shall, in all instances, commence within the first seven days of the term, and shall be continued to within seven days of it.

QUACK DOCTORS IN INDIA. — An incident characteristic of epidemics in India is mentioned by the *Indian Medical Gazette*. During a recent outbreak of cholera in Rungpur, the measures adopted by the medical authorities were already bearing fruit and the people were beginning to appreciate the value of the rules which had been issued for their guidance when a number of quacks, termed "ojhas," alarmed at the falling off in their profits, made a concerted attempt to defeat the efforts of the government. Under the pretext of exorcising the cholera demon, they levied a fee of one rupee in every household, while they personated the "demon" at night, prowling with torches on the outskirts of the villages, and terrifying the simple natives by the utterance of the most hideous yells. They succeeded, further, in spreading a report that the recent census had proved the country to be overpopulated, and that the government doctors had consequently been sent down to poison a certain number of the inhabitants. The result of these rumors

was so disastrous that in many districts the people deserted their villages and fled to the jungle, and the local authorities experienced the utmost difficulty in persuading them to return.

#### NEW ENGLAND.

MEDICAL PRACTICE IN CONNECTICUT. — It appears that energetic action is being taken in the State to obtain a satisfactory medical practice law when the legislature again meets. Many newspapers of the State have taken up the crusade in favor of a bill which has been prepared, and which is said to be favored by the different so-called "schools of medicine" in the State. Connecticut is one of the few States in which no such law has as yet been passed.

TYPHOID FEVER IN WAKEFIELD, MASS. — A large number of cases of typhoid fever have been reported in this town during the last fortnight. Most of the cases occur in the same locality, and among the employees of the Wakefield Rattan Company.

#### NEW YORK.

THE HEALTH OF THE CITY, as indicated by the number of deaths reported during the week ending September 5th, still continues very good. Taken altogether, the summer mortality has been very low this year, and the deaths of children under five years have been proportionally much below the average. During the week mentioned the total number of deaths reported was 736; which was 90 less than in the week preceding, and 42 less than the average of the corresponding weeks of the past five years. It represents an annual death-rate of but 22.72 to the 1,000 of the estimated population. With the exception of scarlet fever and diphtheria, the mortality from contagious diseases was very low; and the number of deaths from these two affections, namely, 9 and 22 respectively, was but slightly larger than the average for the corresponding week during the past five years. The number of deaths from phthisis, bronchitis, pneumonia and Bright's disease were all below the average.

TENEMENT-HOUSE VISITS. — The Board of Health's Summer Corps of Visiting Physicians completed its work in the tenement-house districts on September 5th. During the past two months these physicians have visited over thirty thousand houses and families, but fewer cases of sickness were found than in any preceding summer.

CENTENARIANS. — On September 5th all the shops in the village of Atlantic Highlands, N. J., were closed for a time in order to allow the population to attend the funeral of "Aunt" Mary Butcher, who died a few days before at the age of one hundred and four. It is stated that two brothers, each over ninety, and a sister, aged eighty-five, survive Mrs. Butcher. On September 9th there died in Morris County, N. J., Mrs. Mary Gallagher, who had celebrated her hundredth birthday last May; and this is the third female who has died at the age of over a hundred years within a few months in the same county.

## Miscellany.

### THE MEDICAL REGISTER FOR NEW ENGLAND.

THE seventh edition of "The Medical Register for New England"<sup>1</sup> has recently appeared. No book is more often used by the busy practitioner than this very complete compilation of just that kind of information which is so often wanted, and, without the Register, so hard to obtain. No less than one hundred and seventy-seven associations, societies and clubs, national or local in New England, are described, and in most cases a list of members given. Each New England regular school of medicine or allied science is described in full. The list of hospitals and dispensaries, one hundred and fifteen in number, is especially valuable. A physician may here see at a glance exactly what kind of case is received, the rules of the institution, or obtain any other information which he would be likely to seek. Miscellaneous facts of various kinds, not coming under the titles of the preceding, also appear.

As in previous editions, the last hundred or more pages are devoted to the personal record, as far as obtainable, of all members of the State Societies of New England, giving their degrees, membership in societies, public appointments, and authorship of papers.

A large amount of work is necessarily expended in revising the Register. The medical profession is constantly changing, men, offices, societies and institutions. This edition is as accurate as can well be made for so intricate a book. It is in every way so complete, and so constantly needed by every physician, that it might well be made the official organ of the New England State Societies.

### BACTERIOLOGICAL RESEARCHES UPON THE SALIVA OF CHILDREN SUFFERING FROM MEASLES.

THE investigations of Mery and Pierre Bouloche<sup>2</sup> lead them to conclude that the pneumococcus and the streptococcus are to be found in the saliva of children suffering with measles, with greater frequency than in healthy children. Broncho-pulmonary accidents rarely appear in connection with measles except in those cases in which the streptococcus or pneumococcus is to be found in the saliva. After death one may trace the pathogenic microbe which has been found in the saliva in the upper air-passages as far as the smaller bronchi. The very frequent presence of the pathogenic agents of broncho-pneumonia in the saliva of children suffering with measles appears to explain the great number of broncho-pulmonary complications with that disease. Hence the necessity of the most vigorous antiseptics of the buccal cavity during the progress of measles.

### OBITUARY. DAVID H. STORER, M.D.

DAVID HUMPHREYS STORER, LL.D., M.D., was born in Portland, Me., on March 26, 1804. He received his early education in his native city. Among his schoolmates was the late Prof. Henry W. Longfellow and the father of Bishop Phillips Brooks. He graduated from Bowdoin College in 1822, at the age of seventeen. He studied medi-

cine in the office of Dr. John C. Warren of Boston, and took the degree of Doctor of Medicine at the Harvard Medicine School in 1825. Always interested in natural history, he helped found, and was an original member of the Boston Society of Natural History, and was a constant attendant of its meetings for many years, serving as its vice-president much of the time. In 1830 Dr. Storer suggested the formation of a private medical school, and within a week, in connection with Drs. Edward Reynolds, Jacob Bigelow and Oliver Wendell Holmes, he established the Tremont Street Medical School which supplied the place of a single preceptor. This was a very great advance in the history of medical education, and was the first move in the new direction of systematic teaching. After this came the summer term of the Harvard Medical School and its subsequent growth to the present time. Between 1836 and 1840 Dr. Storer proposed the foundation of a library for the Massachusetts Medical Society. On the committee with him were Drs. Jacob Bigelow and George Hayward. A member of the Massachusetts Medical Society from 1829, he always jealously guarded its interests. The soul of honor himself, he abhorred every form of quackery and deceit.

His well-known interest in natural history led to his selection by the State of Massachusetts to write a report on the fishes and reptiles of the State. He subsequently wrote a standard history of the fishes of Massachusetts and also a synopsis of the fishes of North America. Appointed as visiting physician to the Massachusetts General Hospital in 1849, he served nine years, and has ever since been one of the consulting physicians. In 1854 he was chosen Professor of the Theory and Practice of Midwifery and Medical Jurisprudence in Harvard Medical School, and most worthily filled the chair for thirteen years, when he resigned. His impressive, impassioned style of speaking drew a very large audience, and made him a justly popular and excellent teacher. For over thirty-five years he was the medical examiner in Boston of the Mutual Benefit Life Insurance Company of Newark, N. J., and till his death was its medical referee of this section. He was an original member of the Boston Society for Medical Improvement, a member of the American Academy of Arts and Sciences, of the American Philosophical Society of Philadelphia and a corresponding member of nearly every important medical society in the United States and of several in Europe, and was at one time President of the American Medical Association.

In 1876 he received the degree of LL.D. from Bowdoin College. He was operated successfully for stone in the bladder by the late Prof. Henry J. Bigelow at the age of seventy-nine. In February, 1889, he was requested by many of his old pupils and contemporaries to sit to Mr. F. P. Vinton for his portrait which should ultimately adorn the walls of the Boston Medical Library Association. He complied with their request, and the result was the attainment of a most superb picture and truthful likeness.

His professional relations with his patients were unusually pleasant. Warm-hearted, sympathetic, genial, kindly, manly, vigorous, active, he made their interests his own, and was idolized by the majority, loved by most, and respected by all. Dr. Storer was not much known of late years as a writer, though as a speaker in the frequent Society meetings he was forcible, logical and trenchant; always ready to uphold the right, but sharp against abuses of all kinds. He was ever ready to extend a helping hand to younger men, and his position of dean in the Harvard Medical School for nine years gave full scope for his kindly feelings. In the foremost rank in the specialty of midwifery and women's diseases, he was naturally selected as one of the few honorary members of the American Gynecological Society at its foundation in the year 1876.

Dr. Storer never held any public office, his time being given strictly to his professional and kindred duties. His private life was simple and unostentatious. Married in the year 1829, he had five children, all of whom have lived to solace his declining years. His wife died in 1885. Of late years, he gradually withdrew from professional work,

<sup>1</sup> By Francis H. Brown, A.M., M.D. Published by Danrell & Upham, Boston.

<sup>2</sup> Rev. Mens. des Mal. de l'Enf., April, 1890.

maintaining, however, his sunny and bright manner as of old. His merry laugh and cordial grasp of the hand welcomed every visitor. Honest, truthful, fearless, upright, just and true, he has served as a model in many respects for younger men, and been an honor to his profession and the community in which he lived.

### THERAPEUTIC NOTES.

**IODINE WATER AND ARISTOL AS SURGICAL ANTISEPTICS.**<sup>1</sup>—Popoff speaks highly of the antiseptic effects of irrigations with iodine water (1 to 10,000), and consecutive powdering with aristol (pure or in the form of a twenty per cent. mixture with boracic acid) in cases of tuberculosis of joints (fungating arthritis, etc.) and bones, callous syphilitic ulcers, simple chronic ulcers, angina Ludovici, phlegmon, furunculosis, wounds of every description, etc. The iodine lotion also gives excellent results in inveterate ozæna. In addition to its powerful antiseptic properties it has a decided astringent and hemostatic action. Under its use luxuriant and profusely bleeding granulations rapidly assume a normal appearance, cease to bleed, etc. The iodine water likewise speedily checks parenchymatous hemorrhage from any recent wounds.

**INCOMPATIBLES OF ANTIPYRINE.**<sup>2</sup>—According to Millard and Campbell, the following substances produce precipitates when added to aqueous solutions of antipyrine: Carbolic acid in saturated solution, tannin, mercuric chloride (soluble in an excess of water), infusion catechu, infusion cinchona-bark, infusion rose-leaves, infusion uva ursi, solution of extract cinchona-bark, tincture catechu, tincture cinchona, tincture hamamelis, tincture iodine, tincture kino, tincture rhubarb. The following substances produce coloration when added to aqueous solutions of antipyrine: Hydrocyanic acid, dilute solution, yellow; nitric acid, dilute solution, weak yellow; ammonia-alum, dilute solution, dark yellow; amyl nitrite, acid solution, green; nitrous ether, alcoholic solution, green; copper sulphate, green; ferrous sulphate, yellow-brown; ferric sulphate, blood-red; ferric chloride, blood-red; syrup iodide iron, red-brown.

### Correspondence.

[From our Special Correspondent.]

#### SEVENTH INTERNATIONAL CONGRESS OF HYGIENE AND DEMOGRAPHY.

##### MILLING AT LONDON.

(Continued from No. 11, page 283.)

THE LORD MAYOR'S ENTERTAINMENT. — DIPHTHERIA. — IMMUNITY. MEAT POISONING. — THE WORKING CURVE OF AN HOUR. PHYSICAL EDUCATION. — WATER-SUPPLIES. — QUARANTINE. SANITATION ABROAD. — DINNER OF THE PUBLIC HEALTH MEDICAL SOCIETY. — USE AND ABUSE OF ALCOHOL. INFLENZA. — TUBERCULOSIS.

LONDON, August 21, 1891.

On the evening of Tuesday, the Lord Mayor and Lady Mayoress of London entertained the members of the Congress at the Guildhall. All the arrangements in connec-

tion with this great reception were carried out with perfect success. Several concerts were in progress in different parts of the building during the evening, including one by Mr. Thomas, the Queen's harpist, with a corps of female players, another by Goldfrey's band, etc.

On Wednesday, the time was occupied, in the Section upon Preventive Medicine, by papers and discussions upon Diphtheria. Dr. Seaton opened the discussion with a brief statement of his experience with the disease as it had occurred in different parts of London.

Dr. Schrevels, of Belgium, stated his belief that diphtheria was concurrent with typhoid fever, with reference to the time and severity of its occurrence. He advocated early notification of cases and strict isolation, for its prevention.

Dr. Hewitt, of Minnesota, gave a brief sketch of the history of diphtheria in Minnesota. He concluded that diphtheria, as it had appeared in his State, was more common among women than among men, between the ages of twenty and thirty years, accounted for by the fact that cases were mostly nursed by women. Forty-four per cent. of all cases occurred below the age of five years.

Dr. Bergeron, of Paris, followed with a paper on the "Spread of Diphtheria in Europe in the Past Fifty Years." He gave a *résumé* of the history of its progress, and advocated isolation, and the closing of schools in infected districts.

Dr. Gilbert, of Havre, said that a special crusade was carried on by an organization called a *brigade de salubrité*, which insisted upon the prompt notification of cases and the disinfection of unhealthy localities. He believed it could be stamped out by strict measures.

Dr. Abbott, of Massachusetts, gave a history of the disease in that State, with tables conforming to those published by Dr. Longstaff. Assuming the mortality in dense districts (those in which there was less than one acre to each person) as 1,000, the medium districts of the State (having more than one acre, but less than two acres to each person) had a mortality of 803, and the sparsely settled districts (having over two acres to each person) had a mortality of 609, these figures, being compiled from 32,517 deaths which occurred in the State from 1871 to 1888, inclusive. Many other facts relating to its prevalence in different parts of the State were presented, and the following conclusions stated:

- (1) That diphtheria is an eminently contagious disease.
- (2) That it is infectious, not only by direct exposure of the sick to the well, but also through indirect media, such as clothing and other articles that have come in contact with the sick.
- (3) That the certainty of infection is not so great as in the case of some of the other infectious diseases, notably small-pox and scarlet fever.
- (4) That overcrowding, faulty ventilation, and filthy condition of tenements favors its spread.
- (5) That the influence of defective plumbing is not proven.
- (6) That its transmission through public and private water-supplies is not proven.
- (7) That its propagation is favored by soil-moisture, damp cellars, and general dampness of houses.
- (8) That the poison may remain ineffective in houses for a long period.
- (9) That density of population favors its spread.
- (10) That public funerals promote its spread, but that an infected house in which a funeral is held is quite as liable to spread the disease as the body of a person who has died of diphtheria. A living, breathing person sick with diphtheria is more liable to communicate infection than the body of one who has died of diphtheria.

Dr. Charles Paget offered a paper intended to show a "difference in the susceptibility of old and new residents to diphtheria."

The discussions in the Section upon Bacteriology were devoted wholly to the subject of immunity.

Dr. Roux read a paper describing the experimental methods of Pasteur.

<sup>1</sup> British Medical Journal, Supp. Medical Local, August 21st.

The principal paper of the session in this Section was that of Mr. Hankin, of Cambridge, who detailed the results of many experiments upon animals and summed up his remarks with the following proposition: "Immunity, whether natural or acquired, is due to the presence of substances which are formed by the metabolism of the animals rather than by that of the microbe, and which have the power of destroying either the microbe, against which immunity is possessed, or the products on which their pathogenic action depends."

His classification of defensive proteids was as follows:

		Myco-sozins:	Alkaline globulins from rat (Hankin), destroying anthrax bacillus.
	Sozins:		Toxo-sozins:
	Defensive proteids present in the normal animal.		Of rabbit, destroying V. mitschlikovi poison (Gamaleia).
Defensive proteids (Hankin)		Myco-phyllaxins:	Of rabbit, destroying pig typhoid bacillus (Emmerich).
Alexius (Buchner).	Phyllaxins:		Toxo-phyllaxins:
	Defensive proteids present in the animal after it has artificially been made immune.		Of rabbit, etc., destroying diptheria and tetanus poisons (Behring and Kitasato, antitoxin of Tizzoni and Cattani).

A very lively discussion ensued in which Drs. Emmerich, Arloing, Kitasato, Ehrlich, Klein, Fodor and Metschnikoff participated.

A great deal of interest was manifested in the paper of Dr. Edward Ballard, upon "Meat Poisoning," which was read in the Section upon Animal Diseases related to Man. Dr. Ballard's extensive experience as an officer of the Local Government Board of England enabled him to contribute a paper of unusual value. His conclusions were as follows:

(1) The phenomena which we speak of as "food poisoning," productive now of one and now of another sort of definite malady among consumers of certain foods, are claiming, on ever-growing evidence, to be regarded as true infective diseases, as much so as scarlatina or tuberculosis.

(2) In infected food capable of producing disease on being eaten we find one, or both, of two things—a living microscopic organism and an organic chemical poison of greater or less virulence.

(3) Of these two things, that which is immediately operative in the production of the morbid phenomena is the chemical poison which is apparently of a basic nature and a product of the processes of bacterial life.

(4) Specifically different bacteria capable of producing this chemical poison may, through its agency, give rise in the human system and in animals to clinical phenomena and pathological changes in the organs which are so similar that at present they cannot be distinguished.

(5) Given the bacterium and favorable environment, the bacterium may grow, multiply, and produce its own special chemical poison from the material which affords it nourishment either outside the body or within it. One important element of environment is temperature. If a bacterium will not grow at the temperature of the body, it, of course, will not produce its operative chemical poison when introduced into the system.

(6) Moreover, both the bacterium that produces the chemical poison in an infected food and the chemical poison itself may apparently be evanescent; perhaps in the former case the bacterium being killed by its own products, and perhaps in the latter case, because the chemical poison undergoes destructive changes. Hence an infected food, poisonous when eaten at one time, may fail to be poisonous when eaten at a later period, or poisons when innoculated at one time may cease to be so later on; or one portion of an infected mass of food may be poisonous, and another part not be so.

(7) It is to be observed that in many cases of food-poisoning an incubation period has been distinctly traced, in others it has been less obvious; in some there was practically none, only from half an hour to a few hours elapsing between taking the food and the initial symptoms of the malady.

(8) As regards the kinds of animal food which in the adduced instances produced miscellaneous or fatal results: Of the fourteen instances food was or consisted largely of:

Pig meat of one kind or another in . . .	9 instances
Veal . . . . .	1 instance
Beef . . . . .	1 instance
Butcher's meat (kind unstated) . . .	2 instances
Tinned salmon . . . . .	1 instance

I am disposed to think that this is no unfair representation of the relative frequency with which swine's flesh thus gives rise to specific diseases of the kinds referred to, as compared with animal food from other sources.

(9) The grand precaution of all is the very commonplace one signified by the word cleanliness. Every factory where pork is converted into brawn or hams ought to be so arranged that light and a draught of air can penetrate freely everywhere; there should be no corners where refuse matter can lodge and become a centre for the cultivation of morbid micro-organisms in filth; the rise of ground air should be obviated by cement under the pavement or flooring; and the place should be kept scrupulously clean and free from incursions of sewer air or putrid emanations of any kind. Kitchens, and above all pantries and places where food is stored in hotels, public refreshment rooms, or pastry-cooks' premises, and in private houses, should be similarly cared for. It should be held to be part of the business of conservators of public health to see that these rules are observed, as well as the business of every master or mistress of a family.

A paper was read by Professor Victor C. Vaughan, of the University of Michigan upon "The Infection of Meat and Milk." The subject was discussed under the following heads:—

(1) The infection may be due to a diseased condition of the animal from which these foods are obtained.

(2) The infection may be due to the inoculation of these foods with specific pathogenic micro-organisms outside the body of the animal from which they are derived.

(3) Meat and milk, especially the latter, are often infected with saprophytic toxigenic bacteria.

In the Section on Infancy, Childhood and School-Life, a very interesting paper was presented by Dr. Leo Burgerstein entitled "The Working Curve of an Hour."

The writer presented the results of an experiment conducted in a school having two classes of girls and two classes of boys, 162 in all. Examples in simple addition and multiplication were given requiring the use of 135,010 figures. Mistakes increased as the fatigue became greater. Dr. Burgerstein concluded that, (1) it is desirable that the subject of mental over-pressure should be investigated by exact experimental methods; (2) until the question of over-pressure has been carefully investigated in a proper scientific spirit, school-lessons generally should not last longer than three-quarters of an hour.

The principal paper of the day in this Section was that of the chairman of the committee on Physical Education of the School-Board of London, George White, Esq., the subject being "Physical Education." The writer advocated the practice of having in connection with every schoolhouse, either an open air-space out-of-doors, under a large shed, or a hall in the schoolhouse, to which each class may go in turn for exercise, or as an undesirable alternative, plenty of floor-space in each class-room, unencumbered by desks, well-lighted and ventilated. He advocated the teaching of swimming in the public schools, and said that no school can be said to have its educational machinery complete which does not include ample accommodation for teaching its boys and girls how to swim. The London School Board has lately provided swimming baths for both sexes in some of its new schools.

The reading of this interesting paper was accompanied

by frequent exhibitions of exercises by a class of children, under the direction of Miss Harrison, a teacher in one of the London Schools. A discussion followed which was participated in by Lord Meath, Dr. Brown of New Zealand, Dr. Burgerstein, and Professor Robinson of Maine.

In the Section upon Engineering, M. Beechmann, C.E., of France, presented the subject of "Distinct Lines of Pipes for Water of Different Qualities." He concluded, (1) that the ideal supply for a town consists in the uniform distribution of potable water suitable for all purposes; (2) if particular exigencies demand the expedient of a double service supplying two waters of different qualities, only one of these being potable, the double service must not be introduced into private houses, where potable water only should be at the command of the consumer.

It appears that in a few towns on this side of the Atlantic secondary supplies of water have been introduced successfully. One advantage gained being the more plentiful use of water for flushing drains, urinals, watering streets, etc.

W. Anderson, C.E., gave a description of his revolving purifier now in use at Antwerp and at Boulogne, and was followed by a paper by Baldwin Latham, C.E., upon the "Influence of Ground-water upon Health," in which he claimed that many diseases (notably small-pox) were materially affected by the level of the ground-water.

In the Section upon Naval and Military Hygiene, in the absence of Dr. Montzambert, of Quebec, his paper upon "Quarantine in Canada and the United States" was read by Dr. Collingridge. He described the administration of Quarantine at the North American sea-ports, and recommended the following requirements for a quarantine station: (1) A boarding station, so placed as to command the channel leading to the port. (2) A boarding steamer, fitted with hospital cabins for landing the sick, and with appliances for disinfecting in the sailing ships' hospitals with the mercuric chloride drench, and with steam, when such disinfection is found to be all that the vessel requires. (3) A reserve steamer to replace the usual boarding steamer on emergency, and — where the station is isolated — to act as supply and mail steamer, for the forwarding of convalescents, etc. (4) An anchorage for vessels under quarantine of observation. It should be placed conveniently for the main establishment, and safely remote from the track of commerce. (5) A deep-water pier. The depth of water at low tide at its end should be at least equal to the draught of the largest vessels coming to the port, with a frontage sufficient for such vessels to moor to it if required. Upon this pier there should be constructed: (a) A warehouse; (b) elevated tanks for disinfecting solutions; (c) a disinfecting house containing steam disinfecting cylinders; (d) sulphur furnaces, engine, exhaust fans, etc., for fumigation. (6) A lazaretto or hospital for the treatment of infectious diseases. (7) Separate accommodation for non-infectious cases from infected vessels in quarantine. (8) Detention houses for the detention under observation, in groups, of "suspects" or persons who have been exposed to infection. (9) Quarters for officers and staff. (10) Telegraphic communication with the rest of the world. (11) Telephonic communication between the different parts of the station. (12) A bacteriological laboratory. (13) A cremation furnace for the disposal of the bodies of those who have died of infectious disease.

Other papers on the same subject were read by Dr. Aignard and by Dr. J. Staphord Taylor, the Medical Officer of Health of Liverpool. The latter recommended that all medical and sanitary matters appertaining to ships should be under the control of the port sanitary authority, that medical inspectors of emigrants and emigration ships should be officers of the port sanitary authority, that the ship doctors should report to the port sanitary authority all cases of sickness occurring during the outward and homeward voyages, that the Quarantine Act be repealed, and if it be thought necessary to retain any of its powers, let them be transferred to the Local Government Board, who could then make regulations for the management of ships infected with plague or yellow fever, similar to those made for cholera.

These papers were thoroughly discussed by various health officers of English and French ports, and by Dr. Woodhull of the United States Army.

Dr. R. W. Coppinger then read a paper entitled "Sanitation Afloat," in which he treated especially of the modes of warming and ventilating modern ships. In the discussion which followed, Dr. Hyade, of the French Navy, gave due credit to the United States for being foremost in providing adequate heating apparatus in its naval vessels.

In the Section upon State Hygiene the principal topics for discussion were "State Control of Homes for the Working-Classes," "The British Law as to the Discharge of Noxious Gases from Manufacturing Processes," and "The Sale of Poisons."

In the Division of Demography the subjects of "Board and Lodging of Work-girls in London," "Migration of Labor," "Tropical Highlands for European Settlements" were presented. A remarkable paper was that of Mr. Haviland, in which the author attempted to show a relation between the prevalence of cancer and the presence of clay and lime-stone soils, in which he was not supported by the disputants who followed him.

A dinner was given on Wednesday evening by the Public Health Medical Society, to which many distinguished guests were invited, Professors Grüber, Brouardel, Pagliani, Drs. Littlejohn and Russell, of Scotland. Sir Charles Cameron, of Dublin, presided, and kept the assembly in good humor by a constant flow of ready Irish wit. Several distinguished foreign representatives were made honorary members of the Society.

On Thursday, in the Section on Preventive Medicine, much interest was manifested in the discussion upon the "Use and Abuse of Alcohol." Sir Dyce Duckworth's opening remarks were a very good plea for moderate drinking, and may be summed up in the following sentences: Total abstinence is for the use of the chronic drunkard; but the sale of alcohol to children under the age of puberty should be made penal.

He was followed by Professor Westergaard, of Copenhagen, whose paper was largely devoted to the measures which had been adopted in different countries for the suppression of intemperance. He criticised the recently published statistics of Dr. Owen, and said that the average age of drunkards at death is a very imperfect measure, since it has no relation to the mean duration of life. In his criticism upon the laws of the United States, he objected to the Maine Law and the Local Option Laws, but favored the High License plan.

The remarks of Dr. Norman Kerr, President of the Society for the Study of Inebriety, were very strongly in favor of total abstinence. He presented many statistics relative to the effects of intemperance in Great Britain. With reference to improvements in the treatment of inebriety, he presented the two following propositions:

(1) By recognizing inebriety (or, as Dr. Kerr had ventured to call it, "narcomania," a mania for intoxication or torpor) as a disease, and drunkenness as very often but an effect or symptom of disease. A fair proportion of such cases, as the experience of the Dalmatye Home for the Treatment of Inebriety and other similar hospitals proved, could be cured.

(2) By amended legislation (the existing Inebriates' Acts applying only to well-off inebriates voluntarily asking to be admitted to a licensed Retreat, under the forbidding requirement of appearance before two justices) to provide for (a) compulsory reception and retention of inebriates too demoralized to apply of their own accord, (b) for reception of voluntary applicants on a simple agreement, without appearance before justices, (c) for the care and treatment of the poor and those of limited means.

Dr. Isambard Owen said that his paper in the *British Medical Journal* had been misquoted frequently, and that he had never arrived at the conclusion, indicated by the figures, that the total abstainer's life was a worse one than the chronic drunkard's; and Sir Vincent Kennett Barrington, in a very clear and able speech, spoke of the connection between drunkenness, lunacy and idiocy, and strongly

upheld the Norwegian restriction system, which had transformed that country from the most drunken to the most sober nation in Europe.

The afternoon was chiefly occupied by Dr. Lisle's paper upon Influenza and the discussion upon it. He inclined very strongly to the theory of personal contagion, and said that this was recognized in some Asiatic countries.

"When influenza exists in Northern China the natives will warn the stranger, and say, 'Dismount at my tent another time.' In England, parties often took place as usual, whilst the family of the host was suffering from the disorder. I wish to insist on the fact that no one suffering from the disease has a right to spread it to others, and that the hospitality of an infected house is to be avoided. Aged people, and those in delicate health, should avoid all contact with patients who have influenza, and, as a precautionary measure, letters and parcels should be disinfected."

In the Section upon Bacteriology the session was chiefly occupied with papers and discussions upon Tuberculosis, Sir Joseph Lister presiding.

Prof. Burdon Sanderson's paper treated mainly of the Etiology of Tuberculosis.<sup>1</sup> He regarded the question, so far as the danger from tuberculous meat is concerned, as being in an unsettled state, and that further experimental research is much needed. His conclusions were, that there are not facts enough as yet to say definitely that tubercle taken by the intestine produces general tuberculosis, but in children tubercles of the intestine are followed by tubercle of the glands and the bones, so that we may infer that the same may occur in the adult; but we are in great want of more experimental research. More evidence is wanting as to the cause of tubercle in infancy. Tubercle should be included in the Infectious Diseases Prevention Act. We still want information as to the actual prevalence of tubercle.

Professor Bang, of Copenhagen, continued with a paper in the same line of inquiry entitled, "The Alleged Danger of Consuming the Apparently Healthy Meat and Milk of Tuberculous Animals." He detailed the results of experiments with the milk of fifty-eight tuberculous cows inoculated into rabbits and guinea-pigs, and concluded that the milk of a tuberculous cow, with udders apparently healthy, is not in the majority of cases dangerous, though undoubtedly so at times. He does not think the muscular tissue of meat a favorable nidus for tubercle bacilli. Further experiments with blood of twenty tuberculous cows were detailed, with positive results in two cases only. He thought the seizure of the meat of every tuberculous animal too severe a measure. It did not appear that he had made experiments in the feeding of the milk of tuberculous animals.

Another paper upon the same line of inquiry was contributed by Professors McFadyean and Woodhead, who took stronger ground in favor of the possibility of human beings contracting tuberculosis through the ingestion of tubercular material from the lower animals. It was now agreed that, although in the later stages tubercular mammitis is readily diagnosed, there appears to be a period during which it is clinically impossible to make it out (except by inoculation of small animals); at this stage tubercle bacilli are present in the milk in very small numbers, though in sufficient numbers to render the consumption of such milk dangerous for weakly children.

Professor McFadyean also remarked that the danger of tuberculous milk was diminished by dilution with sound milk. He thought there was great necessity for a fortnightly inspection of milk cows by a veterinary surgeon. No phthisical patient should be in a dairy. The question as to the danger of eating meat from a tuberculous cow must still be answered, as many thought it to be a local disease. The main cause of tuberculosis is from animals.

Professor Ehrlich made a communication on "Koch's New Method of Treating Tuberculosis."<sup>2</sup>

It is generally acknowledged that the principle of cure resides in the local effects which tuberculin exercises on

the specifically affected tissues. The violent inflammatory reaction passing to necrosis is neither desirable nor necessary, but, on the contrary, light and gradually repeated stimuli producing cicatrization of the tuberculous centres is what is to be desired. The essence of this method of treatment is to retain the specific excitation of the tissues as long as possible, and not to annihilate it, as with large doses is the case. The methods of Moritz, Biedert, Guttman, Langenbrich were described by the author, all of which are based upon the application of small but repeated doses of gradually increasing strength. The advantages of these processes are that the undesirable inflammatory effects of the remedy are avoided. It is specially to be noted that the pathological signs found from tuberculin are produced by large doses.

Professor Cornil (Paris) proceeded to give his experience of tuberculin as a heroic and dangerous remedy, about which we as yet know little, and we run great danger of causing a catastrophe. He then spoke of the danger of disseminating an otherwise localized tuberculosis.

Dr. Bardach (Odessa) related his experience of its use, which was not favorable.

Dr. Hunter remarked on the great differences between Koch's experience and that of others. He described experiments to show the nature of the active principle of tuberculin. He succeeded in isolating: (1) Which gave fever and no local action. (2) Which gave local action and no fever. (3) Which gave neither, but had the remedial effect.

Professor Ehrlich, in replying, remarked that a patient can be gradually brought to bear large doses without any danger.

(To be continued.)

## RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, SEPTEMBER 5, 1891.

Cities.	Estimated population for 1890.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from					
				Infectious diseases.	Consumption.	Diphtheria and scarlet fever.	Typhoid fever.	Diphtheria and croup.	
New York . . .	1,515,301	736	369	29.26	10.22	18.80	1.40	3.92	
Chicago . . .	1,069,850	419	205	31.20	7.68	14.88	9.36	3.84

Peabody . . .	10,158	5	3	40.00	—	40.00	—	—	

Deaths reported 2,966; under five years of age 1,442; principal infectious diseases (small-pox, measles, diphtheria and croup,

<sup>1</sup> See Journal, September 3d, p. 251.

<sup>2</sup> See Journal, September 3d, p. 255.

diarrhoeal diseases, whooping-cough, erysipelas and fevers) 828, consumption 272, acute lung diseases 162, diarrhoeal diseases 512, diphtheria and croup 113, typhoid fever 95, scarlet fever 35, whooping-cough 23, cerebro-spinal meningitis 18, measles 14, maternal fever 11, erysipelas 7.

From scarlet fever New York 13, Chicago and Pittsburgh 5 each, Brooklyn, Baltimore and Lynn 3 each, Philadelphia and Cincinnati 2 each, Milwaukee and Cambridge 1 each. From whooping-cough New York 4, Philadelphia and Milwaukee 3 each, Chicago, Brooklyn, Baltimore, Cincinnati and Pittsburgh 2 each, Boston, Washington and Nashville 1 each. From cerebro-spinal meningitis New York 7, Brooklyn and Lynn 3 each, Worcester 2, Philadelphia, Washington and Fall River 1 each. From measles New York 5, Chicago 3, Pittsburgh 2, Philadelphia, Brooklyn, Cincinnati and Fall River 1 each. From maternal fever New York 7, Baltimore 3, Brooklyn 1. From erysipelas Chicago 3, Brooklyn, Baltimore, Milwaukee and Worcester 1 each.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,405,108, for the week ending August 29th, the death-rate was 18.1. Deaths reported 3,294: acute diseases of the respiratory organs (London) 150, diarrhoea 335, whooping-cough 85, fever 49, measles 53, scarlet fever 20, diphtheria 28, small-pox (Birmingham) 1.

The death-rates ranged from 10.0 in Halifax to 28.5 in Preston, Birmingham 18.7, Bradford 16.1, Brighton 13.1, Hull 15.6, Leeds 17.7, Leicester 20.8, Liverpool 22.9, London 17.3, Manchester 19.4, Sheffield 22.4, Sunderland 26.6.

In Edinburgh 18.5, Glasgow 18.3, Dublin 23.9.

#### METEOROLOGICAL RECORD.

For the week ending September 6, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Date.	Baro- meter.	Thermom- eter.	Relative humidity.		Direction of wind.		Velocity of wind.		W'e't'h'r.	Rainfall in inches.	
	Daily mean.	Daily mean.	Maximum.	Minimum.							
			8.00 A. M.	8.00 P. M.							
			Daily mean.								
			8.00 A. M.	8.00 P. M.

ening, N. snow. O. Indicates trace of rainfall. 0.07 Mean for week.

#### OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 5, 1891 TO SEPTEMBER 11, 1891.

Surgeon DAVID L. HENNINGTON, Surgeon HENRY McE-  
LDERY, Assistant Surgeon WALTER REED, Assistant Surgeon  
CHARLES M. GANDY, appointed members of a board of medical  
officers to meet in New York City, October 1, 1891, for exam-  
ination of candidates for admission into the medical corps of the  
Army.

Leave of absence for fifteen days is granted Captain L. W.  
CAMERON, assistant surgeon, U. S. Army.

Major SAMUEL M. HOBSON, surgeon, U. S. Army, is relieved  
from further duty at Fort Adams, R. I., and will proceed to San  
Diego, Cal., and report to the commanding officer for duty at  
that post.

#### OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING SEPTEMBER 15, 1891.

HEAVY WELLS, surgeon, ordered to special duty in fitting  
out the new Naval Hospital at Portsmouth, N. H.

Dr. H. HALL, surgeon, ordered before the Retiring Board,  
September 15th.

JOHN W. REED, surgeon, ordered, in connection with present  
duties, to report on Labor Employment.

#### APPOINTMENT.

Dr. CHARLES L. WOODBURY, formerly assistant at the  
M. H. S. Hospital, Somerville, has been appointed Inspector of  
Lunatic Asylums, Massachusetts, Board of Lunacy and Charity,  
Boston.

Dr. A. R. MORTON, resigned.

#### RECENT DEATHS.

GEORGE B. LORING, M.D., died suddenly in Salem, Mass.,  
September 14th, aged seventy-four. Dr. Loring was born at  
North Andover in 1817. He graduated from Harvard College in  
the class of 1838 and from the Medical School in 1842. After  
practising in North Andover for about a year he was appointed  
surgeon in the United States Marine Hospital at Chelsea, where  
he remained about seven years, having been in 1849 appointed  
commissioner to revise the hospital system. He removed to  
Salem in 1851, where he was subsequently postmaster for four  
years. For many years he applied himself to practical and  
scientific agriculture. He was a member of the Massachusetts  
House of Representatives from 1891 to 1898. He became presi-  
dent of the New England Agricultural Society at its formation  
in 1894, and held the position at the time of his death. He was  
chairman of the State Republican committee from 1890 to 1895,  
and of the United States Centennial Commission from 1872 to  
1876, and president of the State Senate from 1873 to 1877. He  
was elected to Congress in 1870, and served until 1881, when he  
became United States Commissioner of Agriculture, remaining  
in that office until 1885. In 1889 he was appointed by President  
Harrison as Minister to Portugal, which position he held for  
little more than a year.

D. HUMPHREYS STORER, M.D., M.M.S.S., died in Boston,  
September 10th, aged 87. An obituary notice of Dr. Storer will  
be found in another column.

PETER PINEO, M.D., M.M.S.S., died in West Somerville, Sep-  
tember 10th, aged sixty-six. He was born in Nova Scotia, and  
at the age of seventeen began the study of medicine. After  
serving four years in the office of Dr. Hamilton in Boston, he  
went to the Harvard Medical School, but did not graduate.  
The next year he took a course of lectures at Bowdoin College,  
from which he received the degree of M.D. in 1847. From this  
time until 1861 he practised medicine in Barnstable, and also in  
Groton.

At the outbreak of the Civil War, Dr. Pineo was commissioned  
surgeon of the Ninth Massachusetts Regiment. In August, 1861,  
he received from President Lincoln the commission of Brigade  
surgeon of United States Volunteers, and served in the Virginia  
field in 1861-62 on the staffs of General James S. Wadsworth  
and General Rufus King. During Pope's campaign he was on  
the staff of General McDowell and also served on General  
George G. Meade's staff as medical director of the First Army  
Corps at Antietam and South Mountain. On December 1st,  
while on the march to Fredericksburg, Dr. Pineo was ordered  
to Washington, D. C., to take charge of the Douglas General  
Hospital. In March, 1865, he was commissioned lieutenant-  
colonel and medical inspector of the United States Army.  
During the years of 1863-65 he personally inspected every army  
on the Atlantic Coast from Washington to Texas, and also the  
great hospitals at Fortress Monroe, Norfolk and Portsmouth,  
which, combined, contained nearly 10,000 beds. He was the  
consulting surgeon of Jefferson Davis while the latter was con-  
fined in Fortress Monroe.

In January, 1866, Dr. Pineo returned to Boston and took up  
his residence at Hyannis, on Cape Cod, where for many years  
he was in charge of the Marine-Hospital Service for the district  
of Barnstable, and also carried on a large surgical practice  
throughout that county. In 1880 he relinquished active work.  
The later years of his life were spent in and near Boston.

Dr. Pineo was for forty years a member of the Massachusetts  
Medical Society, was anniversary chairman in 1878, and for  
many years was a councillor.

### THE HISTORY OF INSTRUMENTAL PRECISION IN MEDICINE.

THE PRESIDENTIAL ADDRESS AT THE OPENING OF  
THE CONGRESS OF AMERICAN PHYSICIANS AND  
SURGEONS, WASHINGTON, SEPT. 23, 1891.

BY S. WEIR MITCHELL, M.D., LL.D. HARY,  
*Member National Academy of Sciences.*

GENTLEMEN OF THE CONGRESS OF AMERICAN PHYSICIANS:—The body over which I have the honor to preside meets now for the second time. Amongst organizations of medical men it stands alone as to quality and peculiarity of construction. It is made up of the special societies, which represent among us all the reasonable divisions of which medicine, in a broad sense, seems capable. Each is a group of acknowledged experts; each possesses the highest fitness. A happy thought has brought them together. The result is a meeting of men whose power to teach others is a pledge to that humility which is ever seeking to learn. It has no medical politics, nor is it embarrassed by useless idlers, who look upon such gatherings as merely pleasant social meetings. The critical demands of its component groups dictate its terms of membership. Broadly national, it meets only in the Capital of the nation, with but one object—work, and the training which insures high quality to work. It is here that the open-minded man may feel the broadening influence of intellectual contacts with those who have other limitations than his own; for, indeed there is some fear lest in our divergent devotion to special studies we run the risk that, contrary to St. Paul, the eye may say to the hand, "I have no need of thee"; or the head to the body, "I have no need of thee"; for as to us, also, there should be no schism in the body.

Specialism in medicine is of recent birth. I can remember when older physicians refused to recognize socially a man who devoted himself to the eye alone. To-day we can only look back with wonder at such narrowness.

Specialism in medicine first arose by the wholesome and gradual evolution of the individual specialist out of the general practitioner; but to-day the special physician is medically born, and is too apt to select his branch before he is weaned from the breast of his Alma Mater. You must permit me to think that all such men would be better doctors if they had back of them more years of general clinical labor. A broad-minded student of the eye once said to me (and he was old in his work): "We should all be the better for an hour or two a day in a general hospital ward," and added loyally, "the very great relative perfection of therapeutics of visual disorders is an intellectual risk." And if Cornelius Agnew could say that, we may well fancy—and you will pardon the jest which holds a truth—that a too exclusive study of the eye may result in mental egotism. If men as old as I are ready to acknowledge this danger, believe me that for the young the pursuit of but one line of practice is only too apt to result in an overestimate of their complete fitness, in hasty papers, mere case reports, wild pursuit of novelties, and the production of numberless minor text-books which can have but a selfish use. Said Romberg once to a friend of mine, who gave him

a new American book, "Is the author thirty-five? I will look at it; is he forty? I will read it."

We have all come to admit gratefully the value of specialism in medicine; but he who is watchful over the general interests of his profession must have seen that these subdivisions of labor involve for us certain perils, which are seen on the one side by the general practitioner, and on the other by those who, in a large-minded way, pursue limited lines of work. Medicine does not grow in an even fashion. When watching a saline solution under the lens, you observe some brilliant crystal shoot out in advance and hold its place until the rest, more slowly but surely, join or pass it, you see an image of that which continually illustrates medical progress. To-day it is surgery which wins; a few years ago it was ophthalmology, which, in newly acquired precision, and in predictive accuracy and therapeutic gains, set up for us novel standards of exactness, and enriching our symptomatology, cast light in many directions. The mere physician seemed to be hopelessly left behind, but now again it is pure medicine which has gone to the front.

What the specialist learns, until it is commonplace, is not easily enough assimilated by the mass of practitioners. At last, however, comes a time when it is, and then the whole body of medicine feels the gain in nutrition and repays the debt. The masters of our still most perfect art, medical optics, may wisely remember that it was physicians who most distinctively recognized and diffused the knowledge that headaches and some other brain disorders are due to eye strain, and thus, while lessening our own futile labors, crowded the waiting-room of the ophthalmologist.

I could easily show you, by added proof, what we all lose by not keeping close touch of one another's gains. The criticism of the specialist is that the general practitioner does not early enough ask his help in difficult cases. The largely educated and generally occupied physician feels (and you will pardon your critic) that limitation of attention to organs, the eye, the ear, the womb, is apt to lead to a too entire trust in local means, and to neglect of those patient methods which ought more frequently to call for the added counsel of the general physician. For, now-a-days, the patient often resorts at once to the specialist, and it is the ophthalmologist who sees, or who ought to see, the first signs of specific disorder, of spinal troubles, of asthenic states. Whether justly or not, the thoughtful, general practitioner is to-day distinctively of opinion that the absence of grave mortality after operations which once were so fatal, has created a vast temptation for the younger surgeons.

This critic believes—Is he right? Is he wrong?—that too often and too promptly the gynecologist resorts to but one drug, and that steel in the trenchant form, when perhaps the state of the body makes operations doubtful as to their remote usefulness, or that he condemns to sexual neutrality some who, under patient medical treatment with careful inattention to the sexual organs, might have had preserved for them the inestimable possibilities of the wife and the mother. I once saw, almost by chance, with Marion Sims, a girl of eighteen, decreed, after purely surgical consultation, to lose her ovaries next day. I said that she ought to have a larger chance of medical treatment. Using a rather strong phrase, with energy characteristic of the man, he replied, "I never murder sex without a pang. Let us give her a re-

prive." To-day she is a wholesome, happy wife and mother.

And, too, there is, as I have hinted, the other side of the shield—the general practitioner who sees the beginnings of disease and does not correctly interpret them, or early enough to ask counsel. He regards as rheumatic the neuralgias due to the faint beginnings of spinal disease. He treats headache or vertigo by general means, and allays them by drugs, when in an hour the physician of organs would tell him that it is feeble muscles, astigmatism, ear trouble, or nasal disease, which is the parent of the malady.

We saw in this city eighteen months ago the need for occasional conferences between physicians pursuing different branches of medicine. Upstairs, the Academy of surgery, and downstairs the Association of American Physicians, discussed at the same time the value of surgical interference in typhilitis. One body decided for, the other against, the knife, and if I may trust my memory, the surgeons were for delay.

Did I not observe signs of broadening in the views of specialists, I should have increasing fears as to the usefulness of these specializations of practice. Even as to the alienists, I see the growth of a tendency to put aside the title of "Superintendent of Asylum," and to come into relation with neurologists and with a less restricted professional life; I trust they will not pause there, for as to this I am sure that, until asylums become hospitals, and have their outside staff of attending physicians who do not live in eternal contact with the insane, we shall not develop the best possibilities for the treatment of the alien in mind. Believe me, we cannot safely permit any class of specialists to drift away from general and frequent contact with the rest of us.

As I have mentioned the need for continuous individual cultivation on a broad scale, and for personal consultation, I like to enlarge the plea and call a meeting like ours a general consultation. And this, in fact, it is: a focal point for condensed opinions, for authoritative statements, for criticism from varied standpoints, and for significant indications as to those accepted gains which ought to become, from time to time, a part of the mental equipment of all other special, and indeed of all general practitioners.

I have said that nowhere else has a plan like ours brought together such a body of experts as I see before me. And the large task which the years offer you—what is it? Not only is your organization exceptional in construction, but this Congress has national aspects. It is a collection of the ablest men in the American profession. Let us not lose sight of the fact that much of what, in older lands, is acquired knowledge, is with us to be won anew. Our climatology has yet to be medically handled in full, and as to this and the relation of the seasons to disease, we are helped by the growing usefulness of our Weather Bureau. Nowhere else is there a country in which the extent of territory covered by weather reports is such as to make its results medically available in relation to disease. Even in Europe, the influence of seasons on disease has not yet been fully studied. As an evidence of its peculiar effects here, and of the value of the Weather Service reports as an aid to their study, you will recall Wharton Sinkler's interesting proof that the paralysis of childhood (acute anterior myelitis) is a disease of the summer months. I can but allude, also, to the masterly paper of Morris

Lewis on "The Relation of Acute Rheumatism to the Storm Centres," and, if you will pardon me, to my own study of the "Relation of Chorea to the Weather Curves," and of "Traumatic Neuralgia to Storms"; all of which work were impossible had we not the maps and reports of the Signal Service.

We have, as yet to investigate our countless mineral springs, many of them, as in the Yellowstone Park, unlike any elsewhere known.

The modifications which race brings into the classical types of disease, are also before us for analysis; and, as you already know, the negro is relatively less subject to malaria than the white, and also to some neuroses, as chorea, and probably locomotor ataxia; whilst, as to him and the Indian, we have still much to learn.

And if in climatic therapeutics we discovered the value of dry cold air for certain lung diseases, and have taught and made available camp life to invalids, securing for such and other noble uses parks as large as some European principalities, surely immense triumphs await us in these directions, when we have more completely studied the large alternative means afforded within twenty-five degrees of latitude, and nearly 3,000,000 square miles of varied soil, with every variety as to altitude and geological formation.

The swift social changes of this age and country await too your study in the future, with novel problems as to how the woman is being, and is about to be, influenced by a masculine education, and the acceptance on her part of male standards of work and capacity. All the vast hygienic, social and moral problems of our restless, energetic, labor-craving race are, in some degree, those of the future student of disease in America. From this bewildering spectacle of striving millions, I should like now to ask you, as scholars and physicians, to go back with me a little to more tranquil days, and, amidst the stirred dust of unused books, to catch a glimpse of some of the processes which have gone to the final making of what you so well represent—"Precision in Medicine."

It had long been in my mind to make use of the studies I have made, from time to time, in regard to the introduction into medicine of such accuracy as can only come from the use of instrumental aids. The fact that I was to have before me to-night a set of experts trained to a nicety in modern methods tempted me to think that I should here find an audience appreciative of a chapter of medical history hitherto unwritten. The work grew upon my hands, and my chief difficulty has been so to limit it in the telling as not to task your patience. An hour seems to have been set by common consent as the reasonable limit of human power to listen to one man's talk; and if you will regard this present minute as my starting-point, I shall try not to exceed it.

When I was yet a lad there were then alive men who could recall the day when what a patient said, and the physician saw and felt, were all that a case of disease had to tell him. You cannot now realize the extent of this limitation, because instruments and methods of precision have so interpreted what we merely see, feel and hear, that even though we were again forced to rely upon our unaided senses, we should stand on higher levels of knowledge than our medical fathers. The limitations they suffered under lived or drove them into attempts to classify, and minutely to multiply the signs of disease, until what

they believed they saw and felt represented impossible refinements in symptomatology, and the imagination was called in (as it has been in homoeopathic provings) to assist intellect beyond the boundaries of the possible in observation.

You know, alas! that we now use as many instruments as a mechanic, and that, however much we may gain thereby, our machines are not labor-saving. They force us, by the time their uses exact, to learn to be rapid, and at the same time accurate. Thinking over the number of instruments of precision, a single case may require you to use, it is clearly to be seen that no matter how expert we may be, the diagnostic study of an obscure case must to-day exact an amount of time far beyond that which Sydenham may have found need to employ. A *post-mortem* section used to take us an hour or more, and now, alas! it goes on for weeks in some shape until the last staining is complete, the last section studied, the last analysis made.

These increasing demands upon us are due to the use of instruments of precision, or to accurately precise methods. As in factories more and more exact machines have trained to like exactness a generation of workmen, so with us, the use of instruments of precision, rendering the comparison of individual labor possible, has tended to lift the general level of acuteness of observation. The instrument trains the man; it exacts accuracy and teaches care; it creates a wholesome appetite for precision which, at last, becomes habitual. The microscope, the balance, the thermometer, the chronograph have given birth to new standards in observation, by which we live, scarce conscious of the change a generation has brought about. Certain interesting intellectual results have everywhere followed the generalization of precision by the use of instruments, like the world-wide lesson of punctuality taught by the railway and made possible by the watch. We have so often timed the pulse that most of us can guess its rate, and constant use of the thermometer enables one to trust better one's own sense of heat, as the hand appreciates it. If, indeed, you use the sphygmograph much, you get to making visual images of the pulse-curves whenever you very carefully feel a pulse. There is a crude illustration of the yearning after this sort of result in a paper on the pulse, as far back as Fouquet, in 1768. His curious diagrams of the pulse-curves, as they appeared to his mental vision, I have put on the board.

A better example of the training given by instruments is the fact that a careful study of Harrison Allen's work, with Maybridge's photographs, at last, enables the unaided eye to see in truthful order both the swift changes of convulsive acts and the normal movements of man. The subject is a tempting one and admits of much illustration.

Were I not talking to a selected group of experts, I might also dwell on the risks our instruments of precision bring to the lazy or the unthoughtful; as when one looks only at the readings of his thermometer as placed in the axilla or mouth and neglects the temperature of the extremities, or, cheated into satisfaction by the trusted certainty attained as to single symptoms, loses power or desire to reason on the grouped relation of the complex phenomena of disease. For unless men keep ahead of their instrumental aids, these, to coin a word, will merely dementalize them, and but measurably lift the mass without in proportion advantaging the masters of our art, who were so

easily masters in days when the erudite touch was more uniquely advantageous than it is to-day.

Come back with me, then, you who are veterans in observation, drilled to use every engine of research, come and see the first growth of that instrumentally helped precision, which so many here have usefully advanced. The story has its romance; its broken hopes; its failures; its heroes, now lost to memory, and, too, its moral lessons. The pleasure it has given me makes me wish that our great schools possessed chairs of medical history, and that amidst our too busy life more of us could acquire some part of the interest which for me the history of my art has always had. Without the great Library of the Surgeon-General, I should have had no story to tell you; but, even good as is that noble collection, it has failed me in the last year as to some twenty books I wanted. One of them was not in any London library, and one was lost from its place in the great French Library. What I shall ask you to hear will be but a sketch, and even of this I must omit in the reading a too large part.

All the lives of Galileo were not in any American library, and it was seven years before Quaritch found for me the one book of Sanctotius I finally needed. A valuable essay could be written about this whole subject. The history of the balance in medicine is yet to be told; that of the microscope has been enough dwelt upon. We want a book about medical discovery somewhat like Whewell's "History of the Inductive Sciences."<sup>2</sup>

I shall confine myself almost entirely to the story of the earlier efforts to attain accuracy by instruments in the study of the pulse, respiration and temperature. It is not in the books of medical history. In but one of them is there anything interesting. It is here and there in memoirs, journals, lay-biographies, rare old folios and forgotten essays.

The latter part of the 16th and the first half of the 17th centuries was a germinal period in medicine. It saw advances in anatomy and physiology, which led up to Harvey's splendid discovery. It saw, too, the failure of his thesis to influence medical practice immediately or largely. The same period in Italy beheld the first attempts at precision as regards temperature and the study of the pulse. This was the birth era of instrumental accuracy in medicine, but many a day went by before the infant attained to useful manhood. Most strange it is that the seeds of scientific thought as to the first heat records and the pendulum were cultivated in the garden of medicine. Between 1593 and 1597, Galileo, sometime a student of medicine, invented the crude open thermometer or thermoscope.

The thermometer of Galileo was, as I have drawn it, a tube of glass, open below and ending above in a bulb. This bulb having been warmed, the open end of the tube was set in water, so that as the bulb cooled, the water rose in the tube. Then any heat applied to the bulb caused the water to descend, the reverse of that which occurs in the more modern instrument. This coarse thermoscope was obviously a barometer as well as a rude measurer of the change of temperature. A slight gain in the weight of the atmosphere might easily neutralize an increase of heat. It was not an accurate instrument, nor does Galileo seem to have rated it highly since he nowhere mentions it in his works. Others thought more of it. The approximate

<sup>2</sup> A strangely superficial essay, more praised than read.

date of this invention is set for us by one Padre Benedetto Castelli, in a letter about the treatment of a wounded man, written to one Cesarini, in 1638.<sup>3</sup> He calls to mind the fact that Galileo had thirty-five years before shown him the air thermometer.<sup>4</sup> A Venetian noble, Giovanni Francesco Sagredo, writes to Galileo, in 1613, that "the instrument you invented, I have bettered."<sup>5</sup> Sagredo divided the scale into one hundred divisions, and two years later seems to have hermetically sealed the tube, and thus given us the modern instrument. Nevertheless, says Viviani,<sup>6</sup> it was little employed in its improved form; and for years afterwards physicians, as we shall see, made more or less use of Galileo's rude thermometer, of the errors of which Viviani, Galileo's pupil, was well aware. But concerning this invention so carelessly made, raged a battle of words scarcely yet at an end. Renou,<sup>7</sup> in a very full book on thermometers, does not so much as name Galileo. Bacon,<sup>8</sup> Cornelius Drebbel,<sup>9</sup> and, as we shall see, Sanctorius have all described the crude open thermometer. Fludd,<sup>10</sup> in a curious, rare book (*Philosophia Moysaica*, Gouda, 1638), speaks of it, as was then common, as the *Speculum Calendarium* (*Mirror of the Seasons*), and says he got the figure and description from a manuscript more than fifty years old; in another of his works, however,<sup>11</sup> he speaks of the manuscript as being at least seventy years old; clearly no accurate deduction as to priority of discovery can be drawn from such conflicting statements. And finally, Paolo Sarpi was claimed by his biographers to have invented the thermometer. No date was set; but Foscarini, in his work on Venetian Literature,<sup>12</sup> observes that Fra Paolo in his notes speaks of the thermometer, and, according to his recollection, puts the year of invention at 1617.

Much of the early interest as to the thermometer was as to its medical value. I relegate to my notes, or appendix, the bulk of evidence as to prior discovery, which may not be without interest, because it is just where Wunderlich begins fully to tell the story of the modern medical use of thermometers that I shall leave off.

That so eccentric a man as Fludd should have been seriously accepted as evidence is odd enough. He had, as others had, a chance to know what went on in Padua. From the days of Elizabeth every man of fashion, and especially the English, travelled in Italy. Here, too, wandered all who studied, or were fond of science, and it was to Padua—which Sanctorius called the Garden of Science—that Bacon came, and Drebbel, and this same Fludd, and the greater Harvey. The towns of Italy were the exchanges of Europe both for commerce and for science. From them men

took home what they saw or heard, describing them unquestioned (as did Bacon the air thermometer), thus leaving the future critic to settle the question of originality. The temper of the time was not that of our day. Men worked along patiently. There were no journals; the letter or the lecture were the only means of early publication. The genius who to-day invents a new forceps or a new pessary yearns for instant type, and defends his offspring with virulence. Harvey knew of his great discovery in 1616, and it got into print in 1628. His lecture notes show that long before this date he was certain of the matter and clearly knew what he had done. Whence this seeming indifference? If, after his first lectures, some obscure Italian, hearing it, had gone home and stated in a book the facts of the circulation, we should have had a controversy more absurd than those which must have made the ghost of Harvey smile, if in that other world men smile at all.

I have stepped aside to point out how it was that as to the minor, and even greater, discoveries of those days so much trouble arose, or has arisen, as to priority of claim. But it is now with the thermometer in medicine that we are concerned. Galileo, an astronomer, half a doctor of physic, made it; and a Prince, a very great person in his day, Duke Ferdinand II of Tuscany, still further improved it, and constructed divers forms for use in medicine. But this was as late as 1646.<sup>13</sup> In 1876, some of the Duke's pulse thermometers were shown at the South Kensington Exhibition of Instruments of Precision.<sup>14</sup>

In the meanwhile, a new and interesting personage appears on the stage, and with him and the later grand dual inventions and their applications ends for many a day the practical use of the thermometer in medicine. Santorio Santorini, born in Capo d'Istria, April, 1561, was educated at Venice, and at the age of twenty-one took his degree of Doctor of Medicine at Padua. I have put in the appendix (see Appendix D) all that I have gathered as to this notable man, and regret that I have not time here to discuss his claims in full. In his commentary on Galen,<sup>15</sup> I find a description of the air thermometer. The drawings before you are accurate representations of the rude figures in his Commentary on Avicenna.

"We have here," he says, "an instrument with which we may closely measure the degrees of the recession of the heat of the external parts, and with which we may learn accurately, daily, how much we vary from the normal; also the degree of heat of your patients." He does not claim the invention, but says no word of Galileo.

"The patient," he adds, "grasps the bulb or breathes upon it a hood, or takes the bulb into his mouth, so that we can thus tell," he says, "if the patient be better or worse, so as not to be led astray in *cognitione prae-dictione et curatione*." He gives no tables of temperatures, no records. No real good comes of it. The enthusiasm of the inventor keeps it for a while before the public, as we have seen happen in our own day.

The thermometer lacked precision, and even when it had grown into this, want of knowledge of the cause of fevers, of their risks and how to lessen them, caused the mass of physicians to neglect an instrument which,

<sup>3</sup> See Appendix B (2).

<sup>5</sup> *L'Art Veneri*, 1612, p. 229. Edit. Lugdun, 1632, p. 736.

<sup>6</sup> De Nello, *Vita di Galileo*, p. 69.

<sup>7</sup> *Ibid.*, p. 70.

<sup>8</sup> *Ibid.*, p. 81. Galileo died in 1642, having said on paper no word of his invention.

<sup>9</sup> *Ibid.*, p. 69.

<sup>10</sup> M. J. Bacon, *Microscopie Thermometre*, Paris, 1876.

<sup>11</sup> Bacon in *Annotations on the open thermometer* (see A) call it in the end of the sixteenth century, 1629, and again in *Historia Ventorum*, 1638, *et seq.*

<sup>12</sup> Drebbel, born at Alkmaar in 1592, was clearly a charlatan. Of a sort bold, according to De Nello (*op. cit.* p. 83), many wonders, and of a sort credulous as his own Galileo's instrument, but not a genius.

<sup>13</sup> Fludd was born in 1554, and died in 1637. I have described him in the text, and for a description of his instrument see Appendix A.

<sup>14</sup> The scale numbers and aptness of its crude form scattered over a few pages of his book. I cannot describe his statements, but in his *Commentary* the mystic character of his writings is clearly manifest.

<sup>15</sup> Fludd's metaphysical deductions which he draws from the experiment of it, I think we should be very guarded in accepting as scientific.

<sup>16</sup> See *Science Collections, Physics and Mechanics, on Instruments from Italy*, p. 100, *et seq.* Part I, Lib. I, Chap. I.

as yet, had for them little practical value. Here and there as time goes on, in the physiologies, and soon in the books of practice, we find rare statements as to the heat of man.

And now, again, we have to thank an astronomer when, in 1701, Newton marks the blood temperature at  $12^{\circ}$  of his scale, and uses linseed oil as the fluid. A little later Daniel Fahrenheit altered the scale over and over, and at last set  $96^{\circ}$  as the blood heat, and here we come upon the use of armpit temperatures. Boerhaave<sup>16</sup> is said to have suggested to Fahrenheit the use of mercury in his thermometer, as to which there is some doubt; at all events, the records of the famous Paduan Academy show that long before this date the Italians made use of mercury in their thermometers.

Almost a century of silence falls upon medical thermometry. It is broken by a few allusive aphorisms of Boerhaave, and by the doubting sentences of his famous pupil, Van Swieten, in 1745.

De Haen,<sup>17</sup> who saw Avenbrugger working beside him clinically for years, and learned of this genius no lesson as to percussion, more clearly apprehended the value of thermal records. We have re-discovered much that is his; but his methods and instrument were clumsy, and his example proved valueless.

About 1740 appeared in England one of those notable little essays which ought to have had an immense influence. A rude breach is then made in the bulwarks of ancient belief when George Martine<sup>18</sup> follows Gometius Pereira in the view that heats are not specific, and in the proof that heat in man varies only in degree and not in kind. One must have read long and much, to see what a profound hold this doctrine of specific heats had on the mind of medicine. I think there are even yet lingering traces of its tenacity of influence. This book of Martine's is a wonder of able observations. He smiles at the thought of actual ebullitions or effervescences of the blood, as when Willis speaks of it as ready to burst into flame. A poet he thinks may, by his profession (that is good — the profession of a poet!) like Prior in his *Alma* speak of

"Cor to burn, and decur to pierce,  
Whichever best supplies the verse."

There is distinct modern good sense in his sarcastic rejection of "the stomach boiling our food by its great heat."<sup>19</sup> Correcting all former observers, he has the temperature of the skin at  $97-98^{\circ}$ , over or under, he adds. Boerhaave, who made experiments on the effect of heat on animals, says that they die in an atmosphere at  $146^{\circ}$  owing to coagulation of the serum, for, he adds, it is disposed to clot at  $100^{\circ}$  F., and does so not much above that. Around this view was fierce battle, Hales and Arbutnot siding with the great physiological physician. But, says Martine, "I have seen

fevers, most violent, where the blood was, from observation of the skin-heat,  $5^{\circ}$  or  $6^{\circ}$  above  $100^{\circ}$ , without approaching any such danger, that is, coagulation of the serum, or fatal effects." Is it a modern professor, coolly critical, who adds, "Such heat, if neglected or wrongly managed, may indeed dissipate the more thin fields or watery parts, and so thickening the whole mass have had enough effects that way," etc.<sup>20</sup> and then he shows that a temperature of  $156^{\circ}$  is needed to clot serum.

Nor less interesting is it to find amidst notable observations of temperatures these words: "In the ague I had lately, during the height of the paroxysm, the heat of the skin was  $106^{\circ}$  and that of my blood  $107^{\circ}$  or  $108^{\circ}$ ," and further, "what is very remarkable, in the beginning of the fit, when I was all shivering and under the greatest sense of cold, my skin was, however,  $2^{\circ}$  or  $3^{\circ}$  warmer than in a healthy and natural state."<sup>21</sup> This all looks like the beginning of practical use of the thermometer, which then was, or very soon became, accurate enough. The germ of thermometric prognostics is in some of his sentences. But again it falls into disuse, while medicine awaits more correct theories of heat. And here we leave the matter. The physiologists and chemists are busy. There is absolute genius in the researches of James Currie, as late as 1798.<sup>22</sup> But the year 1840 and the systematic work of Andral are reached before that change began, which in Wunderlich's classic made us familiar with the true laws of temperature in disease.

And now, I turn to a not less amazing story of the application of instrumental accuracy to the pulse. I can imagine the discomfort with which you look forward to an essay on the pulse. I can promise that it shall not be dull, and can assure you that nowhere else is it told in full.

An astronomer gave us the first rude thermometer, and it seems to have been another, Herman Kepler, who first, and certainly before 1600, counted the human pulse, or at least left a record of having done this memorable thing. The publications in which he mentions the pulse date from 1604 to 1618. Does it not seem incredible that of the numberless physicians who sat by bedsides, thoughtful, with fingers laid upon that bounding artery, none should have had the idea of counting it? I quote in English what he (Kepler) says.<sup>23</sup> This great but faneiful man seems to have believed the pulse to have some relation to the heavenly motions, and used the time of the pulse in connection with his arguments in favor of the Copernican system of astronomy. He says:<sup>24</sup> "In a healthy man, robust and full of age, in one of melancholic complexion, or in a feeble man, generally for each second there is a pulsation of the artery, with no discrimination between systole and diastole; thus there should be in one minute sixty pulsations, but this slowness is rare, commonly seventy may be counted, and in the full-blooded and in women 80, four to each three seconds. Briefly, in one hour, 4,000, more or less." The clock with which Kepler counted the pulse must

<sup>16</sup> "Ex votis mihi perfecti D. G. Fahrenheit," Boerhaave, *Elemente de Chimie*, p. 94. Says Renou (op. cit.), Fahrenheit changed his scale under advice from Boerhaave to  $24^{\circ}$ . The absolute zero was set at  $0^{\circ}$ , that is, the extreme cold of the winter of 1709 in Holland. The  $24^{\circ}$  marked blood heat. Finally, he divided the degrees into fourths, whence came armpit temperature at  $96^{\circ} = 24 \times 37^{\circ}$ . Other changes came later. It seems clear from Boerhaave's *Chemistry* that he did not suggest the use of mercury to Fahrenheit, for in one place I find that he speaks of *divine Fahrenheit's* idea, and later of having said to have made for his own use such an instrument.

<sup>17</sup> De Haen, *Ratio Medendi*, ch. xi, pp. 7-9, 12, 17-20, 25.  
<sup>18</sup> George Martine, M.D., *Essays and Observations on the Construction and Graduation of Thermometers, and on the Heat and Coagulation of Bodies*, etc. (see edition dated 1725). Wunderlich gives the date 1740 as that of the first edition; I have not seen it. The second edition is in the library of the Pennsylvania Hospital.

<sup>19</sup> Boerhaave, *Elemente de Chimie*. Translation by T. Dallame, pp. 173, 85-165.

<sup>20</sup> Martine, p. 116.

<sup>21</sup> Martine, op. cit., p. 148.

<sup>22</sup> Medical Reports on Effect of Water, Cold and Warm Baths, etc. Falconer mentions Kepler as counting the pulse, as also does Brondont, but neither has any distinct references. I give all the quotations from Kepler which bear on the subject, and for these I am indebted to Professor Asaph Hall, of the National Observatory, Washington. (See Appendix C.)

<sup>23</sup> Kepler, *Opera Omnia*, p. 218 of Vol. VI, published in 1618. The quotations are from the edition of Dr. Ch. Frisch, 1858. (See Appendix C.)

have been such a "balance" clock as his master Tycho Brahe used.

"The next epoch marks a pregnant hour in the history of science.

When Galileo,<sup>25</sup> but eighteen years of age, a student of medicine, counted the vibrations of a lamp swinging in the gloom of the Duomo of Pisa, he conceived them to be in equal time. Desiring to test the truth of his conclusion, he is said to have used his own pulse as a measure of the correctness of the pendulum. Forty years later, in describing the accuracy of his first clock work, he says with enthusiasm, "My clock will not vary so much as the beat of a pulse." Says Viviani, his biographer, "The unerring regularity of the swing of a suspended lamp suggested to the young medical student the reversed idea of marking with his pendulum the rate and variation of the pulse. Such an instrument he constructed after a long series of experiments. Though imperfect, it was hailed with wonder and delight by the physicians of the day, and was soon taken into general use."<sup>26</sup> Unclaimed by Galileo, it was attributed to Paolo Sarpi,<sup>27</sup> and clearly enough was appropriated at a later date by that notable genius, Sanctorius,<sup>28</sup> who also, like Galileo, called it pulsilogon. We have no drawing of Galileo's pulsilogon, but it must have been identical with the simpler form as shown in Sanctorius. It is interesting to observe the tendency towards securing accuracy in medicine thus shown by Galileo at the outset of his medical career; Kepler's works were not published until later, and could not have been fully known to him. With his thermometer and the pulsilogon, and with this picture of his testing the accuracy of the swing of the lamp by his own pulse, this marvellous mind passes out of medical history. Where he would have left it had he remained with us, who indeed can say? Of his loss to us, a poet has spoken:

"Ah! when in Pisa's dome  
He watched the lamp swinging constant in its arc,  
He gave to man another punctual slave,  
And bade it time for us the throbbing pulse;  
Not that grave Harvey whom Fabricius taught,  
Not that Servetus, nor that daring soul,  
Our brave Versalibus, e'er had matched his power  
To read the riddles of this mortal frame.  
And then he left us. Would our strange machine  
Had kept his toil, and cheated heaven's fair stars!"

With the fame of Sanctorius as the discoverer of insensible perspiration, and with the inconceivable success of his aphorisms we have nothing to do, nor yet with his theories, or his morals, which seem not to have interfered with his appropriation of another man's inventions. His works I shall refer to more fully in my appendix.

In his Commentary on Avicenna,<sup>29</sup> he quotes Galen as to "the need to know the amount of departure from the natural state, which is only to be reached by conjecture." But he, Sanctorius, has long been delibera-

ting in what manner the amount of disease could be determined, and has invented four instruments.<sup>30</sup> In his "Vitandum Methodus errorum omnium qui in arte Medica contingunt,"<sup>31</sup> he has also mentioned these. Then he describes what must have been the form of Galileo's pulsilogon. The diagrams before you almost explain themselves; the full descriptive text I give in the appendix.

One represents a scale and a bullet marked with a central white line. We swing the pendulum and note the pulse with the fingers. If the pendulum be faster than the pulse, we lengthen the line; if slower, we shorten it until they coincide. "Then," he says, "we keep this degree in mind until the next day and compare it with a new record. And so we can study the pulse of health and disease." Also he defines the values and defends the accuracy of the pendulum; but of Galileo, not a word. He used the beats of his pulsilogon as a measure of the time one must breathe upon his air thermometer. Other forms are also given.<sup>32</sup> Thus we have to-day a pulse of so many inches (or degrees, if you please), and to-morrow it is longer or shorter, and the fever pulse is short, of course; but of results from all this we hear nothing in these huge tomes. The rest of this story is exasperating on account of its omissions. "These other instruments," he says, "record the frequency and slowness of the pulse, and also the time." "In this" he says, "are seven degrees of the difference of frequency and slowness observed by the index. Then each degree is divided into seven minutes (*minuta*), which are distinguished by the small index." "The construction of the instrument we have described," he adds, "in the book on 'New Instruments for Physicians.'"<sup>33</sup>

This book he refers to more than once, and in his Inaugural Lecture (a rare pamphlet)<sup>34</sup> promises it shortly to his students, and with it also that other, "De Jucundissimis Medicinis." As to both, one is curious, and especially as to this volume upon the most pleasant remedies. Perhaps these manuscripts are yet to be found among the treasures of some old Italian library. And if so, then only shall we know whether these Cotyla<sup>35</sup> were rude watches, as seems likely. He proposes with them to measure the systole and diastole of the heart. To do this, he says, "We must measure expiration, for this we know corresponds to the systole, as does inspiration to diastole."

The explanation of the Cotyla<sup>36</sup> is brief, and now incomprehensible, but we learn that between expiration and inspiration "the artery pulsates twice or in many three times." Finally, we are assured that what other physicians acquire by conjecture concerning the pulse, we are able to attain unerringly by the infallible skill of the pulsilogon. What a comfort he must have found it!

And here the great Paduan professor, with his thermometer and pulse pendulum, disappears from history, dying in Venice in 1636, of a dysenteria (whatever that may be), in the parish of St. Fortun-

<sup>25</sup> Santorii Commentaria, column 21, C. C. Arenberg (list. de la Mechemé) alone gives any competent description of these instruments.

<sup>26</sup> First edition, Fol. Venet., 1620. Close to the not certain date of Galileo's invention, if the Nolle and Viviani may be trusted.

<sup>27</sup> Gal. 76 B, and col. 219 C.

<sup>28</sup> Gal. 76 B, and col. 219 C. Comment on Avicenna.

<sup>29</sup> Appendix D (1).

<sup>30</sup> Com. Arsen. col. 365, and as to Cotyla, Appendix D (2).

<sup>31</sup> I suspect that the dial face in the last Cotyla figured may be merely intended to record the length of the pendulum. But as to this no man can speak to day with certainty. The passage is not clear; and as concerning this latter instrument I see not say that it takes note of the time as does the one before mentioned.

<sup>25</sup> A small Vitellio Galileo, prefixed to an edition of Galileo's Works, published at Florence in 1715. (See page 143.)

etc. Commentaria in primis. Venet., an. Anale wend. for part. I.

<sup>31</sup> Vitellio Galileo, etc. (see above). Gal. 76 B, p. 85, 2. He says: "Breviter hoc est quod Vitellio a pulso never in common use before. This wonder, etc." In his Commentaria in theopoliolum in Paduensi Gymnasio, etc. (see above). Primus Libellus de Avicenna, etc. (see above). There is no pagination. I refer to the end of the summary.

tus,<sup>87</sup> a good saint as a stand-by for life or for death. He lies at rest in the cloisters of Santa Beata Servorum, in a mausoleum which he had made against the time of need. A strange proof of vanity is this care as to how the perishable part of man shall be housed in death. And certainly this man thought well of himself, but was also intensely loyal to our "Mi-stress Art," which he says, in a grandiose way, "is glorious and a helper of men both in peace and amid the din of arms. An art above all others. Folly is it to despise science in general, but to scoff at medicine is not only folly but wickedness—almost the sacrifice of bad hearts."<sup>88</sup> And now instrumental study of the pulse fails us for many a day. When Sanctorius died, Sydenham was a boy of nine. There is not a pulse count among all those vigorous sketches which this great Englishman drew with a master's hand, and only once does Harvey speak of their number, which he says is from 1,000 to 4,000 in the half hour.

Time presses, and I must again leave to a note<sup>89</sup> what lies between Sydenham and the year 1707. Here we come abruptly upon a notable book by Sir John Floyer, Knt. It is called the "Physician's Pulse Watch." He dedicates the first volume to Queen Anne, "for without health," he says, "we should have no relish even for the extraordinary blessings of your reign."

He tells us in his preface, "I have for many years tried pulses by the minute<sup>40</sup> in common watches and pendulum clocks, and then used the sea-minute glass," such as was employed to test the log.

At last he was more happy. One Daniel Quare, a Quaker, had, in the last years of the 17th century, put on watches what Floyer called a middle finger, as we say, a hand.

Floyer's pulse watch ran sixty seconds and, you may like to know, can be had of Mr. Samuel Watson, in Long Acre. He tests this and a half-minute watch which has a cover, by his sand-glass, and finds them not quite correct; one must add, he thinks, five beats.

And now follow pulses of age and youth, pregnancy, exercise, sleep. And we learn how diet, blisters and the weather affect the pulse. Like a good every-day practitioner, he has his fling at science in the shape of a remark on the failure of Harvey's discovery to influence medical practice. Nevertheless, the book, on the whole, is full of good observations<sup>41</sup> thoughtfully carried out. For the first time in medical literature we meet with tabulated results; in fact, there is a modern air about his methods. Clearly he was a shrewd practitioner, a man of scientific accuracy, and knew the world, for he predicts, alas, too truly, that this new method will be sneered at and neglected. As late as 1768, Bordeu<sup>42</sup> dismisses Floyer with something like contempt, and Fouquet qualifies all pulse-

numeration as a mere useless curiosity, and sphygmometric instruments as idle toys. Falconer,<sup>43</sup> as late in the century as 1796, says, "Floyer's methods were unused until now." And this was nearly true. In the 18th century one finds now and then a pulse count, as when Morgagni describes a pulse which beat twenty-two times in the sixtieth of an hour.

If, indeed, any man wishes to nourish a taste for cynical criticism, let him study honestly the books of the 18th century on the pulse down to Heberden and Falconer, or even beyond them. It is observation gone minutely mad; a whole Lilliput of symptoms; an exasperating waste of human intelligence. I know few more dreary deserts in medical literature, from the essay on the "Chinese Art of Feeling the Pulse," with which Floyer loaded his otherwise valuable essay, to Marquet's method of learning to know the pulse by musical notes, an art in which he was not alone.<sup>44</sup> And error died hard. The doctrine of the specific pulses, a pulse for every malady, although rejected by De Haen, is in countless volumes, and survived up to 1827, when Rucco<sup>45</sup> dedicates his book on the pulse to Sir Henry Hallford. Meanwhile whole volumes, like Bryce on Asthma,<sup>46</sup> exist without a pulse or breath count; but farther back, in a queer book on the heart by Bryan Robinson,<sup>47</sup> I find the first clear statement of the proportional relation of the pulse to respiration. Even those among you given to reading the authors of the end of the last and the first twenty years of the present century may be surprised to learn that statements of the numbers of pulse and respiration are very rare in Rush, Cullen and their contemporaries. Heberden<sup>48</sup> and Falconer, who, perhaps, set too much value on pulse counts, made no impression on their contemporaries. In Corvisart on the Heart we hear little or nothing in this direction, and in seven hundred pages of Laennec there is one pulse count and no numeration of the breathing. It seems incredible; but not until the later French school developed its force do we find in reports of cases the beginnings of those systematic numerations of the breath and pulse which are met with in modern cases.

If German science had been as much the fashion as German literature, the remarkable pulse studies of Nick,<sup>49</sup> 1826, would have sooner wrought a change; but it was not until a later day, and under the influence of the great Dublin school, that the familiar figure of the doctor, watch in hand, came to be commonplace.

I have thought it well to illustrate thus fully the medical history of the watch as an instrument of precision. How small, but how essential a part of pulse study are the numerations it enables us to make accurately, you all well know. We could better lose this knowledge than the rest of what the pulse teaches, and yet it is the only pulse sign we can put on paper with perfect precision, as Heberden remarked an hundred years ago.

I have kept you long, and I fear may have been wearisome, but this tale of the growth of Precision in Medicine is not without its moral. In every modern

<sup>38</sup> Falconer, 1796, who quotes Kepler as to pulse of man 70, woman 80.

<sup>39</sup> As witness Professor Flinck, who in his curious treatise on the pulse, on page 37, has a section embodying somewhat the same ideas.

<sup>40</sup> Rucco on the Pulse, London, 1827.

<sup>41</sup> Bryce, London, 1807.

<sup>42</sup> Treatise on the Animal Economy, Dublin, 1732.

<sup>43</sup> Heberden, Med. Trans. 1 vol. Phys., London, 1758.

<sup>44</sup> Nick, Beobachtungen ueber die Bedingungen unter denen die Haengigkeit des pulses in gesundem Zustand verandert wird Tubingen, 1826.

<sup>87</sup> And of St. Hermagora.

<sup>88</sup> From "An Oration delivered by Sanctorius Sanctorius, at his Installation as Professor of the Theory of Medicine, Anno Salutis, MDCXII," appended to a lecture on the Life of Sanctorius by Capello, published in Venice in 1750.

<sup>89</sup> To realize how vast was the advance made by Floyer, one should read "De Variatione ac Varietate Pulsus," David Abercromby, London, 1685, and Scheelhammer's "Disquisitio Epistolica de Pulsu," Helmstadt, 1690. These are among the last works of the 17th century on the pulse. The history of the pulse is very well told in the Dublin Medical Journal, vii, p. 36, by Forney, but is nowhere related with competent fairness.

<sup>40</sup> He wrote various other books, notably Gerocoemica, 1721. In this he alludes to the pulse watch "to be made by making the middle finger of the watch large, and to run round the plate." He gives tables in this book also of the pulse and weight of urine.

<sup>41</sup> Save the queer chapter on the "Chinese art of feeling the pulse, which seems to have taken the fancy of many able men.

<sup>42</sup> Ed. of 1768, p. 13.

century were men who sought to secure it. The true rate of advance of medicine is, however, not to be tested by the work of single men, but by the practical capacity of the mass. The truer test of national medical progress is what the country doctor is. How useful, how simple, it seemed to count the pulse and respiration, or to put a thermometer under the tongue, and yet it took in the one case a century, and in another far more, before the mass of the profession learned to profit by the wisdom of the few.

A certain sadness surrounds these stories of medical discovery. I have resisted the temptation to tell you more of Currie's notable essay, and of what little notice it won until Hufeland saw and proclaimed its value. The fate of Avenbrugger, the inventor of percussion, and of his little book, so small, so terse, so wonderful, is yet more pitiful. He foresaw its future and his own, saying in his preface (1760): "*Enim vero invidia, livoris, odii, obreptationis, et ipsarum calumniarum socii, nunquam defuerunt viris illis, qui scientias et artes suis iuventis aut illustrarunt aut perfecerunt.*"

Avenbrugger lived on to see his famous colleague, De Haen, write his fifteen volumes without a word on percussion. Van Swieten did it no greater justice. In his huge history of medicine, Sprengel mildly mentions it as rather subtle. Yet were the contents of this booklet of twenty-two pages,<sup>60</sup> more practically valuable to man than all these men wrote or all the results of the vast and bloody campaigns during which it slept, until in 1809, one year before the grave, contented German died at eighty-seven, Corvisart translated it into French, and proclaimed its undying value to a waiting world.

And now I have done. It seems to me, as I reflect on what I have said, that I have told you a long story of neglected inventions or discoveries, ending sadly in repeated failures to make on their time any permanent impression of the real usefulness of the work accomplished. It is not only the poet who has to wait, and may never see the morning light of recognition break upon his genius.

In my mental wanderings amongst these numberless essays—these great folios—which are too often but splendid monuments, inclosing dead and forgotten thought, I have seen how strong was the resurrective force which now and then existed in some little essay long neglected, how from it, as from seed, arose in after-years a fresh growth of vitalizing thought, and how this story repeats itself over and over, until, at last, what one knew and valued becomes the riches of all.

Assuredly in our day this process is more speedy than in the distant past. But be this true or not, there must be many among you who know that apart from large human acceptance, and the material compensations of professional success, there is that in the mere pursuit of truth which mysteriously rewards from day to day. This can no public or personal lack of recognition destroy, no indifference affect. I doubt not that such consciousness of duty done must have sustained many of the men whose failures to see their work result in larger use oppresses one who reads the story of medical discovery. Over and over, they pre-

dict their own failure to influence their fellows. The poet is grieved by the indifference of his contemporaries, but the physician seems to be made philosophical by the steady influence of every-day work, so that not Marcus Aurelius could have been more content than Avenbrugger, whilst a half century passed by half scornful, and would not see the royal gift he offered to mankind. I am glad to think he was happy, and to know that for all of us, as for him, this incessant every-day work is a talisman of success, a fact which none know better than those to whom I now say, at last, my thanks and my farewell.

## THE PRESIDENT'S ADDRESS

AT THE OPENING OF THE SESSION OF THE ASSOCIATION OF AMERICAN PHYSICIANS, WASHINGTON, SEPTEMBER 22, 1891.

BY WILLIAM PEPPER, M.D., LL.D.

To those who share the feelings of close relationship which the earnest and friendly meetings of our Association have fostered among us, it will not seem strange that I pause, before proceeding to our scientific work, to speak of our fellow-members who have been taken from us during the past year.

Hosmer Allen Johnson, a founder, trustee, and professor of the Chicago Medical College, and one of our original members, died February 26, 1891, at the age of sixty-eight years. In the truest sense of the words, he was an ornament to our profession. Dignity and elevation of character, blended with rare charm of presence, conferred additional distinction upon his high scientific and literary attainments. His memory will be cherished not only in the city of his adoption, but by all who had the privilege of his friendship.

James Kingsley Thacher, Professor of Physiology in the Medical Department of Yale University, and an original member of our Association, died on April 20, 1891, at the age of forty-four years. Descended from a line of ancestors eminent for vigor and originality of intellect, Dr. Thacher early displayed rare powers as an investigator and thinker. It was not until the age of thirty-three, and after he had won international distinction by his researches in comparative anatomy and physiology, that he began the practice of medicine. He rapidly attained the front rank of the profession, and during the remaining years of his life his frequent contributions to medical literature were of exceptional value as embodying the work of a highly-trained scientist dealing with problems of practical medicine. It is difficult to overestimate the loss sustained in the early death of one who so well illustrated the highest type of the physician—the student of Nature as revealed in the functions and disorders of the human body.

Richard Lea MacDonnell, Professor of Clinical Medicine in McGill University, had been a member of our Association but a short time when his death occurred on July 31, 1891, at the sadly early age of thirty-five years. He possessed gifts and ability of high order as clinician, as writer, and as teacher. He had already accomplished much valuable work, and was so well equipped in purpose, powers, and position that a brilliant career was confidently expected. The Association has lost in him one of its most promising members.

<sup>60</sup> Avenbrugger's little book was printed at Vienna in 1761. It was translated into French by L'abbé de la Roche. This, and a book of mine, written by the translator, shared the fate of the original. The latter's French translation was in 1905. So long slumbered a wonderful invention.

Out of our short list of honorary members, Fordyce Barker and Joseph Leidy have gone. Dr. Barker died May 30, 1891, at the age of seventy-three. His long life seemed all too short for the countless acts of courtesy and charity which he found place for in a career rich in professional and social success. The delightful charm of the man almost threw into shade the remarkable gifts of the physician. His tact and urbanity were perfect, and his hospitality boundless, so that he was the paragon of hosts. The affectionate solicitude with which he lavished on his patients, rich and poor alike, the resources of his skill, made him one of the most successful and beloved of physicians. His large-hearted sympathy and benevolence made him eager in the organization and service of all movements for the relief of suffering and the elevation of his fellows. The rich treasures of his experience and his strict scientific integrity made his publications valued in all parts of the world. These many honorable distinctions made it eminently proper he should be placed on the list of our honorary members, and in his death we all have to lament the loss of a dear friend and a cherished colleague.

In the death of Joseph Leidy, which occurred on April 30, 1891, at the age of sixty-eight years, the medical profession in America lost its most-loved and honored member, and American science its most illustrious representative. It makes a difference to the world when such a man passes away. At his birth, Nature gave him her *accolade*, and all his life long he was loyal to the holy quest of truth, which is the vow imposed on those whom she invests as her chosen knights. Who can say how much of the marvellous and inexhaustible knowledge of Nature this great man possessed came from the singleness of his life and the purity of his heart? Who can say how many of the miserable shortcomings we all exhibit, even in our best work, spring from the selfishness and the prejudice we allow to mix with it? Leidy never had a theory to support or a purpose to serve. The all-sufficing motive of his life was to learn the truth of Nature, and to help others to learn it also. To the last, he kept the humility and the simplicity of a little child. No delight could surpass what he felt when new facts were disclosed to him, unless it were that with which he would share with others all he knew. He made great discoveries in various fields of scientific research; but he never seemed to feel any credit was due to him. It merely was that he had chanced first to see that particular fact. It was no achievement of his. Nature had but given him one more little glimpse of her truth. He looked at all natural things with the same fresh, clear-eyed directness. It did not matter by whom, or under what names, or in what surroundings, an object was brought before him; he simply saw the thing itself. In this way he detected blunders innumerable, and became a general referee to whom all sorts of supposed remarkable discoveries were submitted. The certainty with which he could detect the real nature of the object, and the simple, genial way in which he would explain it made irritation impossible. All knew he would treat an inaccurate observation of his own in the same kindly but unsparing fashion.

If only the facts were discovered, it mattered not to him by whom the discovery was made; and windy battles over claims of priority or selfish struggles to pre-empt fields of investigation were alike impossible

to him. More than once he turned aside from lines of research in which he was the pioneer, and where brilliant discoveries were in sight, as soon as he found there were others who longed to win distinction in the same field. I could never see that he enjoyed their triumphs any less than if he himself had won them.

Incapable himself of jealousy or untruth or disloyalty he seemed also incapable of thinking evil of others. In all matters of business he would have been readily imposed upon, and his confidence was freely bestowed on all who sought it. But in the estimation of the scientific value of a man's work he was in many lines of research the very highest and the most candid authority.

Of course he had no enemies. All were united in respect and affection for him. But only those who lived in close and frequent intercourse with him can tell what elevating and humanizing influences this man of science diffused around him. It helped you to be truthful, simple, and liberal merely to meet him and talk with him. I think few men have been more loved by men than he was; and I know not if there be a higher tribute than these to a man's nature. I shall not attempt to tell what Leidy achieved in many branches of science. The mere fact that his scientific contributions numbered fully eight hundred, conveys little idea of the range of subjects they covered; the epoch-making character many of them possessed; or the enormous amount of patient labor bestowed on the thousands of exquisite illustrations they contained. I cannot tell you what he was to his colleagues or to his students in the University of Pennsylvania, where for thirty-eight years he filled the Chair of Anatomy. I feel sure that every colleague in the faculty and every student in the college during that long time was influenced for good by contact with this pure and lovable man. For to Leidy the ever-growing fulness of knowledge brought increasing humility and wonder at the boundless mystery of Nature. And as the close of a profound study of one after another field of natural history, added to his sense of the inadequacy of our powers to cope with the problems of creation and life, his feeling of the necessity of a God of Nature strengthened and deepened. Only a few days before his death, as I stood by his bedside, he chanced to notice the flowered pattern of the carpet on the chamber-floor, and said, "How can they work flowers in a carpet! We love flowers! No one would tread on flowers!" And with his heart full of such gentle thoughts he lapsed into peaceful unconsciousness—like a tired child falling asleep in the bosom of the Nature he had loved so long and so well.

It would seem to me an abuse of a rare privilege were I to add to what I have said more than a few but cordial words of welcome. In thanking my colleagues, the members of the Association of American Physicians, for the honor conferred upon me when called to preside over this meeting, I may couple with these thanks a no less hearty congratulation that the recurrence of our Congress year finds our Association not only instinct with life, and in close touch with what is best and most progressive in medical work, but establishes the fact that participation in the Congress certainly does not detract from the interest and importance of our own meeting.

No less may I join with our warm and brotherly greeting to the distinguished guests who have accepted

our invitation and honor us with their presence, the gratifying claim that the many charms of a visit to this country, and the great pleasure to be given and received in the kindly social intercourse of this week, have not been more potent attractions than the prospect of sharing in the rich programme of scientific work arranged for this Association and for the Congress.

So far at least as medical men are concerned, one need no longer repeat the assurance that when they cross the ocean they change not their feelings but only their horizon. There exists no barrier to our intercourse. The complete solidarity of our science overtops all divisions of race or place. The progress and the interpenetration of knowledge first outgrew personal authority, and have now outgrown the limits of national schools of science.

The existence of this society of clinicians and pathologists is by no means a protest against specialism in medical science. Its presence here in this Congress is typical of the present attitude of scientific medicine to specialism. Just as this great meeting would be crippled without the participation of many special societies, so would our own membership be sadly incomplete did it not include many eminent specialists. General medicine and general surgery to-day are federations of specialists, and the general clinician, even of the broadest gauge, in dealing with obscure and complicated cases, acts but as the leading partner in a medical firm.

This is the natural and desirable development of our professional relations. The courts where the issues of our causes are decided, are open constantly, and have unlimited jurisdiction. The microscope, the ophthalmoscope, the tamatometer, the tests of organic chemistry, are witnesses whose presence is always available, and whose testimony as to matters of fact is unimpeachable. No cumbersome accumulation of papers, and elaborate machinery of procedure hamper our legislation. In the privacy of two or three consulting-rooms are determined with all reasonable certainty and celerity, the issue of causes, vastly more vital to the parties interested, and scarcely less so to the community at large, than those which fill columns in the daily press and block the slow wheels of litigation for years. Remedial measures are agreed upon and carried into effect which require such masterful decision, fertility of resource, and energy of action, as stamp the great leaders in all the hard fought battles of the world.

It is a supreme glory of our service that it is restricted to no nation, no dynasty, no place, no class. The monarch of the nightiest empire and the poorest patient in the hospital ward, command and receive the same efforts in their behalf.

It is by the combination of the highest specialism, wrought by mutual trust and trained co-operation into absolute unity, that the great triumphs of medicine and surgery are now achieved. The evident truth of this is the basis of the work of our Association. The broadening field, the increasing precision of our work; the vast scope of the questions of heredity, of climatic and racial influence, of hygiene and dietetics, of mental and moral regimen — of all that is included in preventive medicine, the great battlefield of the future, and which can be used as far as understood in the methods of the remedial medicine of to-day, call for a co-operation — not local, but national and international

— which shall bring into closer touch, better mutual knowledge and deeper mutual trust all earnest workers in scientific medicine.

It is then with the happy assurance that our work here is in line with the great onward movement of the day, that I announce the opening of the Sixth Annual Session of the Association of American Physicians.

## ORTHOPEDIC SURGERY AS A SPECIALTY.

THE PRESIDENT'S ADDRESS BEFORE THE AMERICAN ORTHOPEDIC ASSOCIATION, WASHINGTON, SEPTEMBER 22, 1891.

BY A. B. JUDSON, M.D., OF NEW YORK.

A FLOURISHING medical society sometimes divides into sections. It is an involuntary process, or at least, one to which the members are forced by the necessity of thoroughly accomplishing the objects of the society. The process may be called an analysis. In the present instance, however, if I understand the organization of the Congress of American Physicians and Surgeons, we have a synthesis. A number of societies voluntarily combine to secure ends which were not contemplated at the beginning of each. A division of labor having been made, according to which each society has its special work to do, it is proper and useful for the societies to meet together for co-operation. Let us therefore briefly consider some of the salient features which mark our specialty of orthopedic surgery. A better knowledge of ourselves will put us in more quick relation with other workers, both general and special, and enable us better to do our humble part in the grand plan.

In common with other specialists, we occasionally hear that we are limited in the possible range of our achievements. The limitation is, however, entirely voluntary, and the work within these limits is practically inexhaustible. If we were not so busy, we might perchance be troubled because we are not always and exactly understood. The sign before an orthopedic hospital in New York is supposed by some of the passers-by to indicate a homœopathic institution. I am probably not alone in having been asked to perform the minor surgical operations of the chiropodist. Many, even among the learned, suppose that the latter part of our name is derived from the Latin word for *foot*, instead of from the Greek for *child*. We are also confounded in the minds of some with the instrument-makers. I mention these things in passing, without a serious thought. If they exist, like morning mist, they will pass away.

It is well, however, to recognize the fact that our practice is comparatively lacking in popular qualities. We have no critical, capital, or brilliant operations. What of brilliancy is there in keeping a limb in such an attitude that the weight of the body in locomotion shall be a favorable, instead of an unfavorable agent, until the natural growth of the member results in comparative symmetry; or in controlling the environment of the diseased joint and the patient, so that the natural processes of recovery and repair shall have their triumph, while the limb is daily growing in symmetry and ability with the growing child? This is not bold surgery, but there is great pleasure in watching and reverently assisting these constantly recurring natural miracles. And will any of us forget the delightful

friendships made among our little patients, their pretty bashfulness, their ready confidence, their irrepressible cheerfulness, their graceful acceptance of what is, alas, inevitable? The combination in them of childish and heroic qualities is a daily wonder. To watch them at play is like a dream in which the birds and wild flowers are enacting a tragedy and improving the precepts of Stoic Philosophy.

Our practice is not only lacking in brilliant achievements, but it is also uninviting, because, as a rule, our patients do not make absolute recoveries. There is always, or nearly always, a residuum of disability and deformity, and in this is to be found perhaps one reason why our specialty has existence; for, what general practitioner would lightly assume the care of a case so exceptional in his practice, and so momentous as those which fall into our specialty?

The why and the wherefore of specialties, in general, and ours, in particular, are questions of interest. Some will say that we have a natural aptitude for mechanics, an inherited preference for slow and sure methods, compared with those that are quick and uncertain, or an inborn reverence for what is physically demonstrable. These personal characteristics may explain why some of us are orthopedists, but I believe the reason why our specialty exists and thrives, is to be found in the desire of the public, the final arbiter, that experts should be invited to bear the responsibility of orthopedic cases.

One very attractive feature of orthopedic practice, is its *reality*—for want of a better word. It is especially the domain of physical demonstration, where the acceptance of pathological doctrine, as well as therapeutic precept, must be preceded by absolute proof. Here, subjective symptoms are forgotten in the presence of objective signs. The data for diagnosis are visible, palpable, and measurable. Treatment is by forces whose action is nicely directed, increased, diminished, and accurately measured. The very weight of the body is duly considered in trauma and therapeutics, and finally the results of treatment are recorded in degrees of a circle and fractions of an inch. Dealing thus, as we do, with physical realities, it is well for us to keep our eyes open to the moral verities also, which no less form part of the tissue of our daily professional work. Let us remember that diligence is the price of success, and that the only desirable success is that which is reached by the rejection of error and the loyal recognition of truth.

Since our last meeting, there has occurred the death of one of our corresponding members, whose hostility to error might in all friendly criticism, be called intemperate, one whose diligence and devotion to the interests of his patients make him an exemplar worthy of our affectionate remembrance. But I will not trespass on the subject of the first paper of our session, which is by Dr. A. J. Steele, of St. Louis, on the orthopedic work of the late Mr. Thomas, of Liverpool.

*Mrs. Green* (to young physician, whom she has called in haste)—“Oh, doctor, doctor! I fear you have made a terrible mistake! My daughter had that prescription which you sent her last night filled, and took a dose of the medicine. Now she exhibits every symptom of poisoning. Oh!”

*Young Physician*.—“Prescription, madam? Why, that was an offer of marriage!”—*Puck*.

### MODERATELY CONTRACTED PELVES.<sup>1</sup>

BY RAY W. GREENE, M.D., OF WORCESTER.

I BRING to your attention to-day the subject of moderately contracted pelves, in the hope that many of you will think it profitable to discuss some of the phases of this vital question. Since the department of obstetrics makes up so large a share of the work of the general practitioner, this subject deserves, it seems to me, more universal attention. Springing from this subject are questions which on the one hand affect beyond calculation the most sacred interests of the family, for the life of a mother and her child is in peril; on the other hand, the physician is confronted with complex problems, which, for their solution, appeal to the resources at his command in the art and science of midwifery, and to the sanctions of conscience as well. Indeed, no greater responsibility can come to any of us than when obliged to decide upon some action which means the sacrifice of human life though yet unborn; or when our decision by inaction may entail a more terrible calamity, because possibly a needless one, the sacrifice of the mother as well. Furthermore, are we justified in violating the course of nature by procuring a premature birth, with the hope of doing little or no injury to either and saving the life of both?

In treating these questions, let no one infer that I seek to bring into controversy the religious aspect of the case, while I keep in mind the highest duty of our profession, namely, to save life, and that the life of the mother is paramount to the life of the child. The limitation which I have put upon my subject, moderately contracted pelves, precludes those cases which we can easily decide must terminate fatally but for the prompt execution of some one of the major operations, like craniotomy or Cæsarian section. Nevertheless, the pelvis of moderate contraction is not without its dangers to both mother and child, and the treatment of such cases demands closer study and more deliberate judgment than those of a more pronounced type. And here it is that the appropriate treatment brings the highest rewards.

The three cases which led me to look up this subject came under my observation within a six months, and are as follows:

*Mrs. M.* came under my care at the completed term of the first pregnancy. I was summoned early of the morning of February 24, 1891. She is of American birth, average height, twenty-seven years of age; been married eighteen months. Since eight years of age, she has been more or less delicate, owing to slight injury to spine at that time, which some years later developed caries of the lumbar vertebrae, leaving a depression in that region which disappeared under treatment of many months in a New York hospital. There followed a slight impairment of locomotion, and after a fall some three years ago from a hammock, striking on one hip and side, she has not been able to stand on her feet without help, more from fear, as she expresses it, than from any other cause. The general health has been very good of late, especially during the pregnancy. On inspection, there appeared no deformity of the spine. The pelvis was symmetrical,

<sup>1</sup> Read before the Massachusetts Medical Society June 9, 1891, and recommended for publication by the Society.

the hips on the same level. The thigh and leg muscles were much atrophied.

The pelvic measurements were, namely, anterior superior iliac spines,  $8\frac{1}{2}$  in.; crests,  $9\frac{1}{2}$  in.; exter. conj.,  $7\frac{1}{2}$  in.; inter. conjugate,  $3\frac{1}{2}$  in. There seemed to be a greater inclination of the pelvis than usual, and the promontory of the sacrum was exceedingly prominent. The labor, which had begun at 1 A. M., February 24, and the membranes rupturing an hour later, progressed very slowly. The head was located at the fundus on right side, with back toward left. The fetal heart heard very distinctly on all sides of the umbilicus. By vaginal examination at 10 A. M., found a foot presenting, the os admitting one finger, with the cervix but little taken up.

During the evening of same day, the patient was seen by Dr. L. Wheeler, at which time the os was dilated to size of silver dollar, cervix taken up. The pains were only of moderate intensity and came at long intervals. He agreed with me as to the grave prognosis for the child. We decided that there was no indication for interference with the labor. On my first visit of the second day, 7 A. M., I found the patient had rested some, with the aid of a small dose of chloral and opium. The os was now fully dilated. During the forenoon the pains did not improve much in power or frequency, so that the patient was somewhat fatigued and more nervous. After thirty-six hours of labor, ether was given and the body was easily extracted, but the head was firmly held at the superior strait. In this work I was ably assisted by Dr. G. O. Ward, and it was with the greatest difficulty that our combined efforts succeeded in getting the head through. Attempts were made to get the extended arms down, but only succeeded in getting one out before the head. The fetal heart, which was strong and regular before the operation, beat faintly for one-half hour after birth; but all efforts (lasting nearly an hour) to resuscitate the child proved unavailing. The child, a male, weighed  $6\frac{1}{2}$  lbs. The bones of the skull were firm; the biparietal diameter measured  $3\frac{1}{2}$  in. The third stage of labor was normal. The patient recovered from ether well; the pulse was of fair strength, about 130. One hour later, the patient suddenly went into a collapse. The pulse was scarcely felt at the wrists at times, during the next two hours. The usual treatment for shock was inaugurated. For two days, the mother's condition was most critical; gradually improvement set in and convalescence, though slow, was marked by nothing of special interest.

The second case is that of Mrs. A., American, of more than average size, twenty-seven years old; married a few years. Always had good health. In October, 1886, her first pregnancy was terminated by a difficult labor, lasting several days; delivery finally accomplished after craniotomy. In May, 1890, the patient, being about two months pregnant, placed herself under the care of Dr. Leonard Wheeler, who asked me to see the case and make pelvic measurements. Taking the measurements independently of each other, our figures very nearly coincided, so that the average were as follows:—

Anter. sup. spines,  $9\frac{1}{2}$  in. Crests, 10 in. Exter. conj.,  $7\frac{1}{2}$  in. We were quite surprised in not being able to reach the promontory per vaginam, from the fact that the walls of this passage were marked with contracted tissue, which seemed to shorten the vagina, and we could in no way push the vault up quite to

the extent of a finger's length. By estimation we placed the inter. conjugate diameter at  $3\frac{1}{2}$  to  $3\frac{3}{4}$  in. The outlet of the pelvis seemed ample. As the family were exceedingly anxious to have a living child, I agreed with Dr. Wheeler that premature labor at the eighth month offered the best chances to secure this end.

Under most thorough antiseptic precaution, in the thirty-sixth week, Dr. Wheeler inserted a bougie into the uterus. Two days later, no pains appearing, Barnes's dilating bags were used effectively, and an easy labor of a few hours gave a living child, born in the O. L. A. position; weight,  $6\frac{1}{2}$  lbs. It required but little manipulation to get the child started in life, and its later development has been most satisfactory. It now weighs 19 lbs., being seven months old. The convalescence of the mother was perfectly normal.

The third case. Mrs. M., American, age thirty-one, married, average height, quite corpulent. From an obstetrical point of view, she has an eventful history. From August, 1881, to January, 1890, she was eight times pregnant, with following results: three miscarriages in the third or fourth months, with adherent placenta; one breech, which died in utero near full term and retained two weeks after its death; one footling, which died in being born; three vertex presentations, two of which were delivered alive with forceps and now living; one died in birth (forceps delivery). I saw her in the maternity-ward of the Worcester City Hospital, in Dr. Wheeler's service. The pelvic measurements were taken by Dr. Wheeler, Dr. Ward and myself. While not exactly the same, the average might be as follows: at the ant. sp. spines, 11 in.; crests,  $11\frac{1}{2}$  in.; exter. conj.,  $7\frac{1}{2}$  in.; inter. conjugate,  $3\frac{1}{2}$  in. March 15, 1891, supposed to be the thirty-sixth week, at noon, the bougie was placed in the uterus and held by cotton tampons in vagina. Labor began little after midnight, and in  $3\frac{1}{2}$  hours child was easily born in good condition. Girl, weighing 5  $\frac{1}{2}$  lbs.; length, 18 in. Mother had normal convalescence.

Cases like these well illustrate what I mean by the term moderately contracted pelvis. If asked to put it in figures, I should say that pelvis of the flat variety and justo-minor type, whose internal conjugate diameter measures not less than 3 in. and  $3\frac{1}{2}$  in. respectively, would come under this head.

Dr. Edward Reynolds has given the best and latest statistics on this subject, which are found in the last number of *Gynecological Transactions*, under the title of "The Frequency of Contracted Pelvis among American Women."

While this abnormality is comparatively rare in this country, it is very difficult to state the exact frequency, from the fact that so little attention has been paid to the subject. It seems more than likely that more cases would be found if we were looking for them. How frequently it is that the diagnosis of contracted pelvis is simply a guess, from the fact that the labor was tedious.

Too often, after hours of futile effort, the weary doctor is satisfied with the diagnosis volunteered by some old-time nurse; namely, "That patient is too close built, sure." No measurements are taken; in fact, he knows as little about pelvimetry as the latest methods of cerebral localization. It is also overlooked that many abnormal positions are due to the contractions of the pelvis, and the doctor is satisfied to have

made out the position, he attributes to it all the evils which follow, without thinking to discover the cause (if any exist) of the malposition.

A dwarf, a humpback, or the ankylized hip would suggest to the dullest or least experienced observer the more than possibility of an abnormal pelvis. But it is also in large and otherwise well-developed women, as in the two cases cited, that slight contractions are found. These cases also well illustrate the way in which most frequently the attention is first called to the pelvis, that is, by one or more difficult labors. Such a history being furnished, the physician would indeed be negligent should he not ascertain the exact condition by measurements, which alone give positive proofs of deformity. Such measurements, to be of value, must be most carefully taken, more than once, with a mind unprejudiced by the history of the case or the theory of any other observer. The measurements of most practical value I have mentioned in the histories of the cases cited.

The text-books very rightly devote considerable space to pelvimetry. The directions should be well studied and frequently practised to insure accuracy. In some cases, there is abundant room for error. In taking the external conjugate, it is with difficulty that you can be sure of your posterior landmark, especially in patients at all corpulent. This measurement should never be substituted for the internal measurement, by which the true conjugate is estimated. To be sure, there are cases where the promontory of the sacrum cannot be reached, especially in the later part of pregnancy and during labor, when the presenting part interferes; but more often the cause of failure is due to the fact that too many have never been taught or never acquired the art of thorough pelvic exploration.

In addition to actual measurements, it is important for the physician to be able to estimate any deviation from the normal in the pelvic outlet, the inclination of the pelvis, the depth and inclination of the symphysis pubis.

Having secured all the facts in the patient's history, and with a definite idea of the impediments to normal labor, the physician's judgment and skill are now severely taxed in devising his course of action. Here no absolute rules can be laid down. Any procedure must be influenced by the many questions which arise, like the following: the condition of the mother and child, the presentation, the size of the child, is the patient primipara or multipara, whether seen at full term or before.

To consider the treatment in all its detail would greatly exceed the limits of this short paper; therefore, I will make my discussion of the treatment centre about the cases given.

Here, in the first place, we have a primipara at full term when first seen, membranes ruptured, os but little dilated, pains weak and at long intervals. Measurements confirm our suspicion of contracted pelvis. The internal conjugate  $3\frac{1}{4}$  to  $3\frac{1}{2}$  in. The presentation is a foot. Here there can be but little difference of opinion as to treatment. The child is evidently vigorous, and the condition of the mother demands no immediate interference.

Our duty, then, is to make every provision possible for the maintenance of the good condition of the mother, for the labor is likely to be a long one, and it is desirable at least that the cervix become well dilated before any untoward event compel us to assist

in the delivery. Inasmuch as the mortality of this presentation in a normal pelvis is by no means inconsiderable, only a guarded prognosis for the child could be given to the family. We were conservative enough to wait several hours after the os was fully dilated (the mother and child being in good condition) in the hope of getting stronger pains.

In interfering after thirty-six hours of labor, we expected by effecting a speedy delivery to relieve the mother and save the child. In this we were disappointed. Had we been able to get out quickly the extended arms, I think we might have saved the child, where the internal conjugate was but a trifle less than the bi-parietal diameter of the child's head.

Take this case again: with the exception that the head presents instead of a foot, would we have been more likely to have saved the child? To be sure, in slight pelvic contractions there are cases where spontaneous delivery has taken place, the child being born alive. But in this case the contraction is more than a slight one. The all-important factor in spontaneous delivery is wanting, namely, strong pains. Besides, the greater than normal inclination of the pelvis would, it seems to me, be unfavorable to a speedy engagement at the brim, even though the pains be tolerably strong. It might be said that had the vertex presented, we would have had better pains; but that is unlikely, from the temperament of the patient, which is more nervous than muscular. And had powerful pains been present, it is more than likely that the patient's strength would have been exhausted long before the head could be moulded through the superior strait. In hoping for a natural delivery, we are not justified in allowing the labor to be long continued, without progress, at the expense of the vital forces of the mother. Take it for granted that the child is alive, what assistance should be rendered? Shall it be forceps or version or perforation?

Just as natural labors sometimes occur in contracted pelves under favorable conditions, so likewise the forceps, while theoretically contraindicated, may be of service in supplementing the natural forces. The objections to forceps are that they tend to increase the diameter of the fetal head, which is already too large for the pelvic conjugate, and otherwise disturbs the normal mechanism so that an unsafe amount of traction force is made necessary. The chief objection to the use of the forceps in these cases is the immense amount of harm they are capable of inflicting upon the mother. I will admit that the unskilful operator is many times the cause of these injuries, rather than the instrument. As illustrating the unsatisfactory results of high forceps, I find in Lusk Dr. Harold Williams's figures quoted. He collected 119 cases of forceps applied above the brim. Of the mothers, nearly 40% of the children, nearly 60% perished. Of course, these figures are, in a measure only, applicable to pelves of moderate contraction. "The forceps," says Lusk, "as a means of delivery before fixation of the head, should be discarded, not because it cannot be employed with success, but because its use, even in the most skilful hands, is extra-hazardous."

The forceps being ruled out, the next consideration should be version. Between these two operations, the controversy has been long and bitterly partisan. The French, in years gone by, have given no alternative for forceps, except craniotomy. But the opera-

tion brought into fashion in Great Britain by Sir James Simpson has been quite generally accepted in this country, as an elective operation in deformed pelves. The value of turning is well stated by Barnes, in his lectures on obstetric operations, from which I quote: "The value of turning in moderate degrees of pelvic contraction rests greatly upon the truth of the following proposition: The head will come through the pelvis more easily if drawn through base first than if by crown first." Other great authorities have affirmed this proposition, while others have disputed it. Dr. Barnes says: "I venture to submit that I have made such clinical observations as are equivalent to direct experiments." He cites cases where, having failed in the use of forceps, he does version and delivers the aftercoming head *easily*.

The proposition is proved by these two circumstances: first, the bones of the fetal head overlap more readily at the sutures, when the base entered first; and, second, the head is rarely, or never, seized in its widest transverse diameter. It is seized by the conjugate at a point anterior to its greatest width, that is, at the bi-temporal rather than the bi-parietal diameter.

The chief objection brought against turning in a narrow pelvis is the fact that it exposes the cord to compression, such as occurs in breech presentations. Dr. Simpson and others are of the opinion that a slight projection of the promontory of the sacrum gives a marked hollow on either side, in one of which the cord is better protected than in case of normal pelvis.

Any destructive operation should rarely need be considered in a moderately contracted pelvis, providing due skill and prompt action were shown in the employment of version; having failed in this, we must then resort to perforation to the aftercoming head. But only when the child is dead, or the interests of the mother plainly contraindicate version, should craniotomy be the elective operation.

I am aware that the Cæsarian operation has been elevated of late years from the condition of a "forlorn hope" to a standard which compares favorably in statistics with any of the operations considered. Such specialists as Grandin, of New York, and others, are so emphatic in their endorsements that they would in every case select it before craniotomy, provided the child be alive. They also show such good records from recent hospital practice that they feel warranted in electing this operation in preference to forceps or version, in cases even of moderate contraction when the chances seem against the delivery of a living child. However promising the outlook for the future of Cæsarian section, it must for many years, at least, remain the exceptional procedure with the large majority of physicians in private practice.

In the case of the two other labors which I described, we stand on vantage ground, remote from the necessity of immediate action and in the possession of instructive history. The amount of contraction, not great, is chiefly in the conjugate diameter, which measures from  $3\frac{1}{2}$  to  $3\frac{3}{4}$  inches.

Both the patients are multiparae. In the one case, a child had been sacrificed in the interest of the mother, who well soon succumbed to the long and tedious labor at full term, terminated by an exhausting operation. In the other case, a married life of ten years had been filled with fear and foreboding, as

the termination of each of the eight pregnancies seemed to this unfortunate woman, at least, the very gate of death.

Many of you are doubtless reminded of cases where the woman is carried through repeated pregnancies, expecting safe delivery at term by some lucky procedure, which sooner or later fails to save her life.

We need, then, no apology for violating nature's course in recommending the induction of premature labor. Nature herself sometimes shows the way by producing spontaneous delivery before full term in contracted pelves. The successful issue of these two cases justify the procedure. The statistics in the books are not altogether favorable, but they are misleading. As Professor Dorlin remarks, it is a question of values, which cannot properly be compared, because the cases involved present an endless variety of dissimilar conditions. The only fair way is to compare the results of premature labor with the results of labors at full term in the same patients. Viewed in this way, he reports 19 cases at term, with 41 children, of which 37 died, while in 25 pregnancies premature labor was induced, with 15 living children.

Milne, in the *Edinburgh Medical Journal*, Vol. XIX., furnishes the most remarkable report, namely: six women gave birth at term to 12 children, of which 11 were dead. In the succeeding 38 pregnancies, premature labor was induced, and 35 children were born living.

This operation is undertaken with the hope of saving both the child and the mother, but at all events to make more secure the safety of the mother. The twofold condition which works favorably for the child is the fact that the fetal head is not only smaller, but much more plastic at the eighth month than at full term, so that with less compression and less time it passes through the shortened diameter of the conjugate. The loss of the child is generally due to the fact that the immature vital powers are inadequate to the pressure caused at birth, and to the struggle for existence after birth.

By premature labor, the mother is not simply saved from the hazardous risks connected with the major operations, but from the severe sufferings incident to a long labor at full term, and also from the many lesions consequent upon such labor, which often renders the patient's after life one of endless sorrow. Scarcely any one would take exceptions to this procedure in cases like the two I have described, but would hesitate to recommend it in a case of primipara of the same pelvic measurements. Professor Dorlin makes no difference between multipara and primipara, but applies to either the same treatment for the same degree of contraction. Thomas puts it in a more general way. He says that "wherever it is estimated, or as is far better where it is proved, that a child at full term cannot be delivered except by instrumental or manual means, premature delivery is called for"; and I may add to this conservative statement what many others believe, that the physician is recreant to his duty if he fails to advise it. The degree of contraction demanding this operation is, according to most authorities, one where the internal conjugate measures  $3\frac{1}{2}$  in. or less, and the best time for the operation is the thirty-fourth or thirty-sixth week. Of course, this would depend somewhat on the pelvic measurements, and also on the size of the child. Some writers recommend the thirty-second to thirty-fourth week.

This operation has been too often unsuccessful in the past, in part because the operator has undertaken the task with too little knowledge or appreciation of the important subjects involved. Such as the correct estimate of the size of the pelvis by exact measurement, and of the size of the child by intelligent palpation rather than trust too implicitly in the so often deceptive calculation of the period of pregnancy, the hygienic care of infants prematurely born, the choice of method on the part of the physician, and his close attention during the operation.

When due attention is given to all the details, better results will follow, and this operation will be placed on a scientific basis, in keeping with the recent progress made in the department of obstetrics.

For sake of brevity, I have omitted very much of importance, but trust enough has been said to emphasize by way of suggestion, at least, three things:

(1) The importance of the subject demands a more general study of pelvimetry.

(2) Early resort to version is a safer operation for the mother than forceps, when the head fails to engage at the superior strait, and in many cases may save the life of the child otherwise condemned to craniotomy.

(3) In premature labor, scientifically managed, we have an operation by which an immense amount of suffering may be avoided, and oftentimes a living child secured.

#### COMPULSORY NOTIFICATION OF INFECTIOUS DISEASES.<sup>1</sup>

BY PHILIP BOOEYER, M.B.,  
Medical Officer of Health, Nottingham.

It is impossible with the limits of time and space at my disposal here to discuss adequately, or in all its bearings, the whole subject which such a title as this opens up before us. A brief sketch must suffice. My object will be to state a case plainly and simply for compulsory notification, to enable those who have had no practical experience of its working to form an opinion of its prospective value, and to show how frivolous and premature are the criticisms passed upon it before it has been fairly tried in conjunction with those preventive measures towards the development of which it is simply intended to stand in the relation of a means to an end.

By compulsory notification of infectious diseases we understand the legal obligation to send immediate notice respecting the occurrence of certain infectious diseases to the sanitary authority of the district in which the affected person or persons are for the time being resident, together with a few particulars of place and people for the guidance of the authority. Different persons have been made responsible for the performance of this duty under the several Acts.

In one small class the householder alone is mentioned, he or she being responsible to the sanitary authority. This system of so-called householder notification has been tried in some three urban districts, of which the town of Greenock is one, and has proved a complete failure in all. The cause of the failure is not far to seek. The majority of people do not care to notify unless compelled to do so. Under this system there is practically no compulsion, for in the

event of prosecution for neglect to notify the onus of proving a guilty knowledge on the part of the responsible layman rests with the authority, and such proof in the majority of cases is not very readily obtainable. A case has recently occurred in Nottingham, where a man in good position sent a servant from his house in the town to her home in the country while suffering from scarlet fever, contracted through attendance upon his child, but in which a prosecution has had to be abandoned, because it was found impossible to produce legal evidence of a guilty knowledge of the girl's condition on the part of the master, without resorting to means to secure conviction, which public authorities in such cases are naturally loath to adopt.

This prosecution was instituted under section 126 of the Public Health Act, 1875, but had it been a case of simple failure to notify the sequel would have been the same.

Under the so-called "dual" system, which is that adopted in Mr. Ritchie's Act of 1889, and which was in force prior to that Act in fifteen of the greater towns of England, and in nearly all the smaller urban districts under notification, it devolves equally upon both householder and medical attendant, to notify to the sanitary authority direct. In practice, however, by the tacit consent of all parties, this system is almost invariably allowed to resolve itself into notification by the medical attendant alone. The accuracy of this statement has, I know, been recently called in question, but it is borne out by the unanimous testimony of all those who have had practical experience in the matter.

The "single" system, so highly lauded by the opponents of the "dual," is in force in three considerable towns only, namely, in Bradford, Norwich, and Nottingham.

Under it the medical attendant is required, immediately after diagnosis, to fill up and hand to the householder a printed notification form, which the latter in turn is directed to transmit forthwith to the sanitary authority. So much for the theory of the system. In practice, the notification is left entirely to the medical attendant, who keeps his book of forms at home, and sends his certificate direct to the medical officer of health.

In Nottingham, I have found that out of 1,508 consecutive notifications, 1,360, or 90 per cent., were made by the medical attendant as above stated; 9, or 59 per cent., by the householder in the manner prescribed by law, and the balance, less than 10 per cent., by myself, by officers of my department, by the police, or by neighbors of the affected families.

Before the passing of Mr. Ritchie's Act of 1889, which was made compulsory for all London, but optional elsewhere, compulsory notification was in force under local Acts in 56 urban districts of England and Scotland. Although local powers for its practice were obtained in some cases as early as 1876, it did not come practically into operation, except in a few cases, before 1882. Of the 28 greater English towns, including the metropolis, 17 had adopted it prior to 1889, and 11 had not, London being among the last.

In only a comparatively small number of the towns was a complete schedule of notifiable diseases adopted from the outset. In most cases an experiment was made with two or three diseases, small-pox, scarlet fever, and typhus, or small-pox and scarlet fever only,

<sup>1</sup> Paper read before the International Congress of Hygiene and Demography, Section for State Hygiene, London, August 11, 1891.

and others were afterwards added to the list. In one case no further addition was made until after the lapse of seven years from the outset.

The diseases more commonly notified under local Acts have been small-pox, cholera, typhus, scarlet fever, diphtheria, and typhoid fever. Under the Act of 1889, membranous croup, erysipelas, relapsing, continued, and puerperal fevers have been added. Power has also been given to sanitary authorities, with the sanction of the Local Government Board, to further expand the list by the addition of other infectious diseases, such as whooping-cough and measles.

There is doubtless much yet to be learnt from the systematic study of the prevalence and fatality of many diseases of this class in conjunction with varying conditions of social and physical surroundings, of climate, season, soil, and food supply, and therefore ample grounds for adopting a general notification and registration of cases. We must, however, guard ourselves, as well as warn the public, against supposing that the notification of all such diseases necessarily carries with it in any measure an element of prevention. The health history of our large notification towns during the past few years proves that for the present, at any rate, such is not the case.

The excellent diagrams handed in by Dr. Thorne Thorne to the Vaccination Commission, and published in their first report in 1889, show at a glance the range of mortality during the past forty years, from several diseases in this list, for England and Wales, and are well worthy of a careful study.

Against only a very small section of this so-called zymotic class have suitable preventive measures been adopted, and in their case alone has there been a decline of prevalence and fatality. There are, of course, a certain number of diseases in the enlarged schedule of the new Act, such as erysipelas and puerperal fever, which are found to diminish, as *a priori* we should expect them to, with improved sanitation. It is otherwise, however, with such complaints as whooping-cough, measles, and even diphtheria.

The first two are apparently amenable to nothing but isolation, and for them this has never, up to the present, been attempted. The issue of printed and verbal warnings, and the occasional closure of a school, may comfort the public, but they have very little effect upon the spread of these diseases.

Diphtheria, whatever may be the conditions under which it arises, or which are most favorable to its propagation, undoubtedly spreads very largely by personal contagion, and prophylaxis, without means of isolation, is practically of no avail. But, means of isolation provided, the difficulty remains of determining the diagnosis of mild and doubtful cases.

This difficulty seems likely to be a serious hindrance to the effectual preventive treatment of diphtheria, and the disease is steadily and ominously on the increase in London and many other town districts.

Enteric fever is undoubtedly fostered by insanitary conditions, and on this assumption its notification in any house or locality is often made the occasion of inquiry, inspection, and remedial action, but to what a limited extent only such action is possible the condition of the poorer parts of many of our large towns too plainly testifies. A great deal of endemic typhoid fever is often required, for instance, to induce a sanitary authority to recognize the desirability of abolishing midden privies, of re-organizing a defective system

of drainage, or of providing a public water-supply. There is, however, one fact worthy of notice in connection with typhoid fever for which we should be grateful. Whether it be in town or country there is seldom much difficulty in securing its notification. Impressed with the belief that some discoverable cause must exist, both the medical attendant and his clients are for the most part too anxious to secure its removal to think about concealment.

Scarlet fever and small-pox are the two diseases against which, in recent times, prevention has chiefly directed its energies. Vaccination, isolation, and disinfection in the first, and isolation and disinfection in the second, are the agents by which it has worked.

In the case of small-pox, so great is the popular dread of the disease, that but little difficulty has been experienced in enforcing either vaccination or isolation, or both together, according to the trend of local opinion. The value of notification, when associated with isolation, quarantine and disinfection, completely carried out, finds striking illustration in the immunity of Leicester from small-pox in recent years.

With scarlet fever the case is different. Many towns are now provided with a large amount of hospital space, specially provided for it, and a considerable number of patients are undoubtedly isolated, but even in the case of those towns furnished with the best and most ample accommodation the actual proportion of admissions to total cases has, until quite recently, been exceedingly small. The following figures for Nottingham, where a large number of scarlet-fever beds have long been provided in the town isolation hospital, strongly support this contention.

Year.	Number of Cases notified.	No. removed to Hospital.	Percentage of Removals.
1882* . . . . .	1,029	56	5.4
1883 . . . . .	456	6	1.3
1884 . . . . .	370	24	6.4
1885 . . . . .	300	47	12.0
1886 . . . . .	351	51	15.0
1887 . . . . .	615	275	45.0
1888 . . . . .	643	318	49.0
1889 . . . . .	1,047	745	71.0
1890 . . . . .	563	800	83.0

\* First year of compulsory notification.

Isolation hospitals then have existed in the majority of our large towns for many years past, but their accommodation has not been sufficiently good or ample and they have not been at all generally used, except for such diseases as typhus and small-pox, until within the past few years. A study of the recent health reports of almost any of these large towns will show the truth of this, and will further suggest that the practical adoption by the general public of the principle of hospital isolation in lieu of home nursing, even in the case of those diseases for which many hospitals are now specially provided, must not be looked for at once.

These hospitals have too often been temporary structures of a comfortless if not forbidding aspect, economy in building with a view to early destruction, which, however, was seldom carried out, being the object of first consideration with the builders. That, however,

was a mistaken policy; the hospital must be made, if possible, more attractive and healthier than the home. When this is done, as I am pleased to say, in some cases, it now has been, we shall begin — slowly at first, but certainly and completely in the long run — to secure the end we have in view, namely, the general acceptance of the principle of hospital isolation for the infectious sick of all classes.

Recent experience has taught us that permanent hospitals, replete with every modern comfort and convenience, can readily, and much more readily than the temporary buildings, be kept clean and healthy, and they may with certain precautions be safely used alternately for different diseases. The required ratio of beds to population has been variously stated. Dr. Buchanan, in 1876, laid it down that one bed per 1,000 would probably be the general requirement of the country as a whole. His estimate has been considered excessive, but if it has actually proved to be so in any instance, this will probably have arisen through neglect to use the hospital, and not through a lack of suitable cases for isolation. In estimating, however, the amount of hospital accommodation required by any particular locality it is always necessary to take into consideration such points as the class, occupation, and density of the population, and the local history of endemic and epidemic disease, the mere mention of which are sufficient to suggest the impossibility of laying down a rule applicable to all cases.

The statistics for the country as a whole, as well as those for particular localities, as I have already stated, all go to show that the only modern zymotic diseases which have declined during recent years are (a) those which are known to depend on insanitary conditions for their propagation, and which, therefore, the improved sanitation of modern times will have had the effect of reducing, and (b) those among the personally contagious class for which isolation, and, in the case of small-pox, vaccination have been practised.

It is altogether too early at present to attempt to estimate the full potential value of notification by an appeal to statistics, but adopting the criteria mentioned above, they are found to yield a result by no means unfavorable to it. Scarlet fever and small-pox have markedly declined in the majority of the notification towns.

If we compare the scarlet-fever death-rates of the 10 larger notification towns mentioned above in the decennium 1873-1882, prior to notification, and in the period of eight years, 1882-1889, subsequent for the most part to its adoption, with the corresponding rates of the remaining nine non-notification towns, of which particulars are given by the Registrar-General, we obtain a result strikingly in favor of the former group. I give averages of the death-rates, and not average rates, in order to make due and proportional allowance for the varying experience of separate populations of widely different numerical values.

This method applied to the case under consideration has, I am aware, met with criticism from professional statisticians, but I fail to see how the value of the figures for different towns of various sizes which have made the experiment of exercising certain precautions against the spread of infectious disease under different circumstances of liability, incidence, fatality, and the like, with different degrees of efficiency, can be duly expressed without it. In denoting chemical results, the prices of articles in daily use, the liability to crime

among the several classes of society, such a method is accepted without cavil. Why not here?

## TEN NOTIFICATION TOWNS.

Average of the death-rates, 1873-82	. . . . .	0.94
Average of the death-rates, 1882-89	. . . . .	0.49
Decrease per cent.	. . . . .	-56

## NINE NON-NOTIFICATION TOWNS.

Average of the death-rates, 1873-82	. . . . .	.86
Average of the death-rates, 1882-89	. . . . .	.49
Decrease per cent.	. . . . .	-43

The corresponding figures for small-pox, as might perhaps have been expected, are more favorable even than these, although I have included the figures for 1880 and 1881 in the last group, in order to introduce the epidemics of those years.

## TEN NOTIFICATION TOWNS.

Average of the death-rates, 1873-82	. . . . .	0.067
Average of the death-rates, 1880-89	. . . . .	0.035
Decrease per cent.	. . . . .	-48

## NINE NON-NOTIFICATION TOWNS.

Average of the death-rates, 1873-82	. . . . .	.071
Average of the death-rates, 1880-89	. . . . .	.048
Decrease per cent.	. . . . .	-36

If we take the numbers of deaths instead of the death-rates, the results obtained are practically identical. The average decrease per cent. in the deaths from scarlet fever for the nine non-notification towns is -46 (that for London being also the same), and the average decrease in the ten notification towns -55.

The corresponding small-pox figures are: for the nine non-notification towns -36, for London -71, and for the ten notification towns -52.

The advantages to be gained from notification are so many and so great, and at the same time so manifest, that it would be an act entirely of supererogation to offer to demonstrate them by an appeal to statistics, were it not that attempts have been made to discredit the whole system by such agency.

It must be apparent to any thoughtful person who devotes attention to the subject, that notification, with isolation, disinfection, and the whole armament of sanitary precautions, are the natural and legitimate outcome of revolution as applied to preventive medicine. Powers have been conferred under the earlier Public Health Acts which it would be impossible to exercise with due advantage to the community without the help of such a measure as compulsory notification. By it the sanitary authority is simply made aware of the existence of diseases which are known to be more or less preventable, which it is every one's wish to prevent, and with the spread of which the authority alone possesses the means to cope.

Whatever the suspected vehicle of contagion, whether it be air, food, water-supply, or household fomites, officers of the authority alone can make effectual investigation, and enforce the observance of necessary precautions. They alone can keep watch over the sources of water, milk, and food, can act upon the suggestions afforded by concentration of cases around schools, factories, and the like places, or among the customers of milk-sellers or other tradesmen. They alone can secure the reform of insanitary conditions found in connection with those diseases known to be fostered by such agencies. In fact, I repeat that it must be apparent to all who have eyes to see, that the sanitary authorities alone can exercise due control of infectious diseases as affecting the community, and that without compulsory notification any such work

that they do must be done at a great disadvantage. The history of compulsory notification has hitherto failed to justify the evil predictions that have been made concerning it. Medical men continue to notify, and yet retain the confidence of their patients. In many cases they are glad to have removed from their shoulders the responsibility of deciding upon the necessary precautions to be taken. Only a very small proportion of cases are concealed, and most deaths from infectious diseases are certified correctly. Friends and neighbors, clergymen, and others, it must be remembered, are often alive to the necessity of reporting cases, even if the persons directly responsible are not.

In non-notification towns, owing to the facilities for concealing cases during life, it will often happen that deaths are certified as due to complications, instead of the original disease. I have known this to occur on more than one occasion, and can conceive the possibility of its more or less general practice where sufficient inducement exists. However this may be, it certainly stands to reason that the small amount of concealment that is possible in towns with notification, will be less injurious to the community than the wholesale concealment that is going on in those without it.

All the arguments urged against compulsory notification bear the impress of the weak case that lies behind them. Like every other desirable innovation, it was and is certain to meet with opposition, but the opposition it now has to face is as nothing compared with the storm which attended its first introduction, or that even of civil registration.

When compulsory notification was first adopted in Nottingham, the whole local profession rose in arms against it. During the present year an opponent of the new town hospital scheme, in a full meeting of the Medical Society, was unable to find a supporter in criticising the work of compulsory notification and isolation in Nottingham. Let us not fear opposition. No good cause ever yet thrived without it, and that our cause is good we have evidence in the fact that its sole aim is to promote the health and welfare of the community.

## Reports of Societies.

### CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

SECOND TRIENNIAL MEETING HELD IN WASHINGTON, SEPTEMBER 22, 23, 24 AND 25, 1891.

GENERAL SESSION. — TUESDAY. — FIRST DAY.

THE Congress was called to order by the Chairman of the Executive Committee, DR. WILLIAM PEPER, who spoke briefly as follows:

In appearing thus for the second time to represent the Executive Committee of the Congress of American Physicians and Surgeons, it must be stated that we have felt greatly encouraged in our task by the liberal confidence reposed in us, and by the manifest deepening of professional interest in our meeting. The success of the first Congress in 1888 gave assurance of the value of the new organization. It is now too early to announce, in view of the large attendance on the part of the participating societies; of the presence of so many guests of high distinction; of the admirable

programme of our scientific work, that the second Congress will more than confirm that assurance.

This renewed success owes nothing to the power of novelty; nor does it depend upon any feeling of loyal attachment such as strengthens older associations. The fundamental thought which prompted the organization has proved itself sound. Vigorous and profitable scientific discussion is difficult in large assemblages, and the more so when but a small proportion of the members can be present at successive meetings. So it soon came about in our extensive country that each great branch of medical work is represented by a special National Society, holding annual meetings at convenient times and places.

As many men belong to more than one such society, and as an increasing number of subjects of high importance demand discussion in more than one special body, owing to their varied aspects, there soon grew up the further thought that good results would follow if all the special National Societies should hold, at convenient intervals, a meeting at the same time and place. So soon as this thought was expressed it met with approval. To the proposed conjoint meeting the name of "The Congress of American Physicians and Surgeons" was given. In this, the second Congress, there are fourteen participating societies. It is believed that all the important branches of medical science, with the exception of Obstetrics, are adequately represented.

These societies have relinquished none of their independence or individuality in entering into this federation.

In two out of three years they hold their separate meetings as heretofore; and even in the Congress years the arrangements for each society, the preparation of its scientific programme, the decision as to the number of its sessions and the hours and places of meeting, the selection of its invited guests, the decision as to what, if any, official entertainment shall be provided, are left to their respective officers, and their representatives on the Committee of Arrangements of the Congress.

It is expected that this reservation of complete autonomy to each body will preclude the occurrence of feelings of jealousy or antagonism in connection with the Congress. Motives of personal ambition, save that of an honorable desire to promote the general interests of the profession, have been excluded by the form of organization.

But, however judicious this plan may be, and however successful the Congress itself, the hopes of those who have labored for its establishment will be dashed if the life and work of the individual participating societies are not influenced by it positively for good.

It is no light matter to share in an organization which stands for so much as does this Congress of American Physicians and Surgeons. It is through the participating societies alone that membership in it is to be acquired. So that while, doubtless, each society has already been watchful as to the scientific qualifications of every applicant for admission to its ranks, it is to be hoped that this watchfulness will be doubled by the remembrance that such admission carries with it the right of membership in this larger and more strictly scientific body. While, too, it needs but a reference to the records of our participating societies to show the highly creditable character of their work through successive years, it should surely act as an incentive

to the maintenance of an even higher standard to remember that the level reached by each will affect the fame and force of our Congress, which must clearly be, in a peculiar sense, the exponent of our highest medical attainments at the bar of national and international opinion.

It may be doubted if further steps are needed in the organization of the medical profession in this country. Our great series of local, county and State societies, culminating in the powerful American Medical Association, form a representative system which we regard as the most perfect possible for the entire profession; and to this there has been added, as I have shown, a series of National Special Societies and the conjunction of these in the present Congress.

It would seem as though the friendly and harmonious co-operation of these bodies, animated by the common purpose of promoting science, serving the community and elevating the profession, may be trusted to secure these noble aims.

Dr. Pepper then introduced the President, Dr. S. WEIR MITCHELL, of Philadelphia.<sup>1</sup>

The first scientific matter brought before the Congress was the discussion of the

CONDITIONS UNDERLYING THE INFECTION OF WOUNDS, INCLUDING A DISCUSSION OF DISINFECTION WITH REFERENCE TO TREATMENT OF WOUNDS, OF THE RELATION OF BACTERIA TO SUPPURATION, OF THE RESISTANCE OF TISSUES TO THE MULTIPLICATION OF BACTERIA, AND OF THE EFFECTS OF ANTISEPTIC AGENTS ON WOUNDS.

DR. WILLIAM H. WELCH, Baltimore, Md., said that the presence of certain kinds of bacteria, as an essential condition of wound-infection, is so well established that discussion of this point is not likely to arise. The comparatively simple conception that a wound to which bacteria gains access, necessarily becomes infected, has been greatly modified. The traumatic infections present their own peculiar problems. The doctrine of wound-infection involves the consideration of many varying and often complicated factors relating both to the agents of infection and to the individual exposed to the infection.

The subject was considered under these heads:

(1) What are the micro-organisms concerned in the infection of wounds, and how do they act?

(2) How are we to explain the great differences in the effects produced by the pyogenic micrococci; their apparent harmlessness under some conditions, their fatal influence in others?

(3) What are the ways by which bacteria gain access to the wound?

(4) How often are bacteria to be found in wounds treated antiseptically or aseptically? What are the character of these bacteria and where do they come from?

(5) What are the best means of surgical disinfection?

The observations as to the relative frequency of the ordinary pyogenic staphylococci and streptococci are not altogether concordant. The yellow staphylococcus appears to be more common in furuncles and abscesses than the white staphylococcus. The author had found a white staphylococcus in small stitch abscesses and minor grades of inflammatory disturbance

in wounds treated antiseptically and aseptically, which differs in certain particulars from the staphylococcus pyogenes albus. He suggested that it be called the staphylococcus epidermidis albus. The efforts to differentiate into distinct species the pathogenic streptococci have met with little success. The list of bacilli which may be concerned in suppurative and other inflammatory affections is much longer than was formerly supposed. The bacillus coli communis was referred to. The chief interest of the observations being that they furnish an illustration of the possible predisposition to infection afforded by intestinal lesions, and also give an example of the much disputed auto-infection. Of the suppurative inflammations examined bacteriologically with negative results, may be mentioned abscesses in which the bacteria were presumably dead, several cases of pyosalphix and suppurating buboes, and some abscesses of the liver.

There is reason to suppose that the process of supuration serves a useful purpose, and is one of the most efficient weapons employed by nature in combating invading micro-organisms. Exactly how the abscess formation checks the invasion of bacteria, we do not know.

The quantity of a culture of the staphylococcus aureus required to produce supuration is not the same for all tissues and all parts of the body. There are also variations in virulence of different cultures of the pyogenic cocci. Inasmuch as it is by their toxic products that the pyogenic bacteria do injury, it is not surprising to find that it makes a great difference in the result whether or not these bacteria enter the tissues already equipped with a reserve force of this poisonous material, or whether we must begin the fight unarmed. This matter of accompanying toxins is possibly of great importance in our understanding of the potentialities of the living agents of wound-infection. The differences in virulence found to exist between inflammatory exudates from various sources are much greater than those observed in the cultures of the same bacteria on artificial media.

In regard to the conditions in or about a wound which favor the lodgment and development of pyogenic bacteria, it may be said that anything which interferes with the integrity of the living tissues in a wound is a predisposing cause of supuration. Chemical irritants, such as carbolic acid and corrosive sublimate, favor the development of micro-organisms. A solution of corrosive sublimate, as weak as 1 to 2000, is followed by a distinct line of superficial necrosis. We are not so well informed as to the influence exerted by blood in a wound. Most surgeons lay great stress on hemostasis in surgical operations, while others advise that in certain classes of cases the wound be permitted to fill with blood-clots. Is this a source of danger? Fresh blood-serum does not possess any such germicidal power over the pyogenic cocci as it does over the typhoid and many other bacteria. The power of the living tissues to overcome a certain number of pyogenic bacteria is well recognized, and the tendency of modern surgeons is to respect these tissues more and more, not to destroy their vital capacities by the unnecessary application of strong chemical disinfectants, not to bruise them, not to make them too tense, not to strangle them, not to suffer the presence in wounds, of spaces and foreign bodies which remove bacteria from the influence of the living fluids and tissues.

<sup>1</sup> See page 309 of the Journal.

Of the various ways in which pathogenic bacteria gain access to wounds, that by contact with infected hands, instruments, and other objects offers the greatest danger. The possibility of infection from the air cannot be ignored. Even in wounds treated aseptically or antiseptically, it is not uncommon to find bacteria. The skin may have all sorts of bacteria upon it, but in addition, it has its own distinctive bacteria. After the skin has been thoroughly washed and scrubbed, the prevailing organism will be found to be the white staphylococcus. This is often found in parts of the epidermis deeper than can be reached by any known means of skin disinfection. We can now understand how, without any flaw in the antiseptic technique of the surgeon, this micro-organism may be found present in wounds, and we have here an explanation of the frequent occurrence of stitch abscesses, although the inference should not be drawn that the white staphylococcus is the only bacterium concerned in the production of these annoying complications. How much practical importance attaches to the demonstration of this coccus, the author was not prepared to say. The surgeon with good technique who does not bother himself about this coccus in the deeper layers of the skin is not likely to be severely punished by the behavior of his wounds. Those who put in drainage-tubes and other extraneous substances will have to consider it. Some surgeons, on the basis of researches on the bacteria of the skin, have abandoned skin sutures, the edges of the wound being brought together by subcutaneous sutures.

In regard to the method of surgical antiseptics, it was said that the conditions for efficient chemical disinfection have been found to be far more complicated than was formerly supposed, and the substitution, wherever applicable, of the simple and certain methods of disinfection by heat is to be commended. Chemical disinfectants still have their place for many purposes in the operating room, but their place is not in healthy wounds. Thorough scrubbing of the skin with soap and water by a sterilized brush removes many of the bacteria, but not all, and cannot be regarded as satisfactory means of cutaneous disinfection. Corrosive sublimate accomplishes much less than is generally supposed. The best results obtained have been by a method in which a saturated warm solution of permanganate of potassium, followed by a similar solution of oxalic acid, plays the principal disinfectant rôle, and this is the procedure now adopted in the gynecological and surgical wards of the Johns Hopkins Hospital.

The best plan of sterilizing the skin is shaving, followed for a day or two, if there is time, by some antiseptic ointment properly prepared; the skin should then be washed with *sapo viride* of the German Pharmacopœia, with five per cent. of lysol or hydro-naphthol. Then there should be worn until the time of operation a compress, wet with some liquid non-irritating, antiseptic, such as creolin or lysol (five per cent.), or hydro-naphthol in saturated cold aqueous solution. At the time of operation there should be a final scrubbing with hydro-naphthol soap, with shaving, and then the skin washed with equal parts of alcohol and ether, or alcohol and turpentine. Where there is not time for this, we must content ourselves with the thorough use of the nail-brush, the razor, and antiseptic soap, with the subsequent use of alcohol and ether.

Instruments are best prepared by dry sterilization, as this injures them less than other plans.

In regard to sponges, there is nothing to be added to the well-known directions. It would seem better to use some cheap absorbent material, which after use could be thrown away.

Silk is best sterilized by placing it in a test-tube, then plugging, and keeping for an hour in a steam sterilizer upon two different occasions. Silk-worm gut may be prepared by immersion for a few hours in a one per cent. aqueous solution of corrosive sublimate and then preserving in alcohol. Catgut is best prepared by immersion in benzine or ether to remove fat; it is then dried and soaked for one or two days in a one per cent. watery solution of corrosive sublimate, after which it is dried and transferred to oil of juniper berries, and from this to strong alcohol containing one per mille of sublimate. In this, if desired, it can be boiled. It may be chromicized before putting it in oil of juniper.

The hands, even after having been in contact with septic matter, may be sterilized by the following method: Wash with soap and water, using nail-brush; then wash the hands and arms with flour of mustard, as though it were powdered soap (this will remove all odor); then wash with *sapo viride* (G. P.), to which has been added five per cent. of lysol, creolin or hydro-naphthol; then rinse and immerse in a strongly-colored solution of permanganate of potassium; they are then rinsed and immersed in a solution of oxalic acid, sufficiently strong to decolorize the skin in two or three minutes; the oxalic acid is rinsed off, and the hands may be considered aseptic.

Drainage is probably required only in septic or affected cases.

After an ideal aseptic operation, we need only a sterilized and a protective dressing. In some cases there may be advantage in impregnating the dressing with some antiseptic.

Among miscellaneous sources of infection may be mentioned the use of an unguent applied to the skin to prevent the adhesion of dressing. Experiments have shown that ointments made with even ten per cent. of resorcin or naphthalin, without the application of heat, contain bacteria. The same ointments heated to the temperature of boiling water seem to be sterile, and to suffer only from air contamination.

Dr. ROSWELL PARK, of Buffalo, N. Y., said: The study of wound-infection is inseparable from that of immunity; and when we have learned that which constitutes or favors immunity, we shall have approached nearer that which is now a *terra incognita*. Immunity is a complex condition not dependent upon any single factor; and from pathological interest as well as from clinical importance, our endeavor now must be to analyze the main question of what constitutes or confers immunity, and try to recognize and then solve its various subordinate queries. This statement, too, is inseparable from another which is to the effect that the surgery of to-day should aim to be aseptic and not merely antiseptic, in other words, we should abolish sepsis and not merely aim to antidote it or conquer it when present. The condition of sepsis is a complicated one, consisting of a poisoning by ptomaines, toxins and albumoses having widely different properties. Some of these substances are so antagonistic that one may neutralize the other. In the intestinal canal there are produced poisonous substances which are taken up by the absorbents, but then are filtered out by the liver before reaching the

systemic circulation. It is by virtue of this depurative action of the liver that many cases of septic intoxication in surgical patients are avoided. In a division of the general subject of blood-poisoning, a condition which may be called intestinal toxæmia or entero-sepsis, deserves a distinct place. This occurs not infrequently, and may merge into a condition of sapræmia or septicæmia, but if promptly checked there is a speedy return to a desirable condition both of wound and patient. By no means do all cases of surgical sepsis have their origin in or about the wound.

We have learned a little in reference to the antagonism of different bacteria, and the poisons which they produce. A microbe may enter the system and produce a proteid or albuminose poisonous to the animal, while the introduction of some other substance may neutralize this poison and save the animal. The principle is the same whether the antidotal poison be injected as such or a second species be inoculated by which it may be produced. Brunton has suggested that blisters do good in this way, by an endermic administration of proteids derived from the blood, but so altered in their passage from the vessels, as to have a different effect, and probably by their chemotactic properties. He also suggests that bleeding may act in a similar manner, as it has been shown that the abstraction of venous blood causes an absorption of proteid matters from the tissues, and these may have an action of their own on the tissues with which they come in contact. The benefits of free purgation probably find here their proper explanation.

The term chemotaxis to which reference has been made relates to that faculty possessed by all motile bacteria of moving towards or away from certain substances which seem to attract or repel them. The same power is inherent in the plasmodia or myxomycetes, as well as in various other unicellular organisms, and leucocytes if not other cells of the human body possess the same property. Chemotaxis is spoken of as positive or negative, as there appears to be attraction or repulsion. Among the most actively positive chemotactic substances are cultures of bacteria; these are powerfully attracted by the leucocytes. The effect is the same whether the cultures are alive or have been killed by bolting. The active agent is some product of the life and growth of the bacteria. The leucocytes thus attracted act as scavengers for the surrounding tissue.

These facts have an important bearing upon questions which vitally concern the surgeon. In the light of these researches, it is difficult to see how the possibility of phagocytosis can be denied, and the impossibility of this process looms up in a flood of light when one discusses the phenomena of suppuration or of other kinds of infection as well as of recovery or immunity therefrom. Support of the phagocyte theory has come from the work of Hankin on defensive proteids. From the spleen and livers of various animals he has isolated the proteid which has the power of killing bacteria, and he has found that this, while absent from normal blood, could be obtained from the blood of febrile animals.

The separation of dead and dying matter is a process in which the formation of proteid material figures largely. An important bearing of these facts is on the use of so-called antiseptic agents. The ideal antiseptic is probably blood serum, its parasiticide properties being in all probability connected with the exist-

ence in it of a globulin which is soluble only in a weak solution of common salt. This may explain the well-known antiseptic action of common salt.

It has been stated that by no means all the sources of sepsis concern the wound itself. The other principal sources of infection may be classified as follows: (1) Previous long-existent toxæmia, as syphilis, diabetes, acetonaemia, lithæmia, alcoholism, malaria. (2) Previous anatomical changes which reduce vitality, as inherited diathesis, old age, amyloid change, chronic and acute nephritis. (3) Recent or acute toxæmia, as uræmia, typhoid, intestinal toxæmia, stercoral toxæmia. (4) Other acute conditions, as starvation, scurvy, anaemia. (5) Conditions of environment, as bad hygienic surroundings. (6) Effect of anesthetics. (7) Effect of antiseptics.

Antiseptics may favor infection in more than one way. Mercurial and iodoform poisoning are not uncommon. When this is established the case becomes one of acute toxæmia. The wounds may fail to unite and suppuration may occur. Again the chemical reaction between the vital fluid and the antiseptic, may cause a loss of the properties of the antiseptic agent, while the tissues on which it acts may have their constitution so changed as to favor rather than resist infection. Investigations make it appear best to keep all antiseptic agents away from absolutely clean, fresh surfaces. The value of blood-serum as an antiseptic has been abundantly shown. This will be poured out in quantity sufficient to serve not only as a cohesive but as an antiseptic agent. The question here arises as to what is the best antiseptic. It would appear that for most purposes peroxide of hydrogen is the ideal antiseptic, as it not merely destroys living organisms, but by oxidation of undesirable and infected material, acts as a scavenger of the tissues. We, however, have yet to learn how to utilize to the fullest advantage the properties of blood-serum.

Direct infection may be of two varieties, self or acute infection and contact infection. The principal sources of contact infection are as follows: (1) Skin and hair. (2) Instruments. (3) Sponges or their substitutes. (4) Suture materials. (5) The hands of the surgeon and his assistants. (6) Drainage materials. (7) Dressing material. (8) Miscellaneous, for example, drops of perspiration, an unclean irrigator nozzle, the nail-brush, the clothing of the operator or bystanders, etc.

Dr. Park presented the following conclusions:

(1) Study of wound-infection and of the septic condition thereby produced is inseparable from a study of what constitutes immunity.

(2) By a study of immunity is furnished the best clue to a due appreciation of the principles of asepsis.

(3) The surgery of the future must aim to be aseptic; for, so far as fresh cases are concerned, we have passed the merely antiseptic era.

(4) Asepsis is to be achieved not alone by attention to the wound and the paraphernalia of operation, but by the closest regard to the patient's organs and tissues.

(5) Sepsis may arise from circumstances and conditions other than those pertaining to the wound itself, although hitherto practitioners have been too prone to scan solely this field when searching for its cause.

(6) Sepsis and infection are combated in more than one way: by natural agencies, and by inherent properties of cells and fluids totally aside from the measures

which the surgeon institutes, and the wisest man is he who studies to take advantage of these vital activities rather than introduce new and conflicting elements from without.

(7) A recognition of the power of chemotaxis possessed by organized and unorganized materials in such varying degree, can be utilized to great advantage so soon as it can be reasonably clearly defined.

(8) A study of chemotactic activity appears to impress one with the truth of the phagocyte doctrine, which, if proven, is one having a large bearing upon the principles as well as the practice of the surgery of the future.

(9) The proteid material contained within cellular infectious organisms both plays such a rôle in causing chemotaxis as well as in poisoning the animal infected, that we have reason to eagerly welcome all knowledge concerning it.

(10) So fast as such proteid material can be isolated, we need among other things, to study its effect upon the commonly used antiseptic agents.

(11) We need to study much further the antitoxic and bactericidal properties of human blood-serum, and the means by which we can avail ourselves of the same.

(12) Some such classification as I have attempted to give of the various causes of lowered resistance to infection, or of the causes of vulnerability or susceptibility, will certainly assist in a due appreciation thereof and will often aid in so fortifying the patient that he may resist infection to which he would otherwise succumb.

(13) The condition of enterosepsis, faecal toxæmia, stercoral intoxication, or whatever it may be called, is certainly one which every practitioner has to fear and against which we should assiduously guard. It is not sufficiently generally recognized and combated.

(14) A sub-form of this condition might justly be made and entitled gastro-sepsis, comprising cases where defective stomach digestion often from dilatation brings about a lithæmic or other toxic condition which favors infection.

(15) Antiseptic agents in the past have worked a revolution in surgical practice and results; we have now reached a time when we know that they all have their disadvantages and also understand how if we are strictly antiseptic in our work we can afford to discontinue their application to wound surfaces.

(16) But the insurance of aseptic character of such work necessitates the use of antiseptic agents of some kind upon everything which may directly or indirectly come in contact with these surfaces.

(17) When this work is strictly aseptically performed, the use of drains or further employment of antiseptics is either an expression of mental uncertainty or of fear. It may be in the interest of humanity, undoubtedly, it often is, but it is not attaining the ideal of scientific work.

DR. ARTHUR T. CAROT, of Boston, referred to the debt which practical surgeons owed to the scientific workers. It is the knowledge of how to obtain aseptic wounds that has revolutionized surgery. Reference was next made to the phagocytic action of the cells and to the germicidal action of the blood serum. The only question is, as to which of these processes is distinctly destructive. The bacteriological action of the blood serum has been proved. These observations may serve to explain some of the phenomena in wound

fevers. It may be that in erysipelas the irritation set up by the application of blisters, iodine, etc., may serve to limit the spread of the disease by the action of the blood-serum on the micrococci of the disease.

In treatment of wounds it is desirable to avoid placing animal sutures in the wound. It is better to close all spaces in the wound by pressure. He had found by culture experiments, that, where the skin prior to the operation was free from organisms, yet, at the close of the operation, their presence could be demonstrated, showing that bacteria had been sown on the wound by the air or otherwise. If necrotic tissue or animal sutures be present, they might constitute a nidus for the development of the bacteria.

MR. THOMAS BRYANT, of London, said that if bacteria are the seed we must remember that the soil is not of less importance. If the soil is not suitable for the growth of the seed it will not grow. No surgeon would operate on a patient except in a case of urgency until the subject had been prepared for operation. In order to prevent the entrance of the germs, irrigation is of service. For that purpose iodine water made by adding a few drops of the tincture or solution of iodine to water is the most valuable. This may be made of a light cherry hue for clean wounds and of a dark cherry for dirty wounds. It also acts as a good styptic, as a dressing he uses wood-wool. The wound is dusted with iodo, one part to one to five parts of boric acid. In every operation there is a certain amount of molecular death, and drainage is required for thirty-six hours. Pressure is better than deep sutures for bringing the deeper parts of the wound in contact.

DR. HAROLD C. ERNST, of Boston: While it is true that nearly all forms of suppurative are attended by bacteria, yet it has been shown that a process answering to supuration can be produced without the action of bacteria. The products of this supuration, however, do not produce activity when introduced into other animals. It has been shown that some of the agents used to destroy bacteria, really favor their growth by diminishing the chemotactic power of the surrounding tissue-cells. Notwithstanding laboratory experiments show the possible occurrence of chemical supuration, it still remains to be demonstrated that the infection of wounds as seen in practice, occurs without the influence of bacterial activity. The most important lessons taught by investigations in this subject, are those which warn us that our pupillage is not yet over and that we are but entering upon the first stage of our knowledge of the processes spoken of here to-day.

MR. JOHN CHENE, of Edinburgh, said that he had assisted Professor Lister during the whole of his time in Edinburgh. The longer he lived the more he believed in the work of Lister and the impress that he had made on surgery. He considered the bacteriological investigations as of the greatest importance, for on these the surgeon must depend in his daily work. Lister long ago spoke of the antiseptic value of the blood-clot, but long before, John Hunter pointed out the value of the blood-clot. The speaker considered that the spray was of great service. The term "integrity of the tissues," had been used by both speakers, but John Hunter had also laid stress on the "vitality of the tissues" which he defined as "the power of the tissues to resist putrefaction." He thought that not only by improving the soil, but by destroying the plant the best results would be attained.

(To be continued.)

THE BOSTON

**Medical and Surgical Journal.**

THURSDAY, SEPTEMBER 24, 1891.

283 WASHINGTON STREET, BOSTON, MASS.**THE CONGRESS OF AMERICAN PHYSICIANS  
AND SURGEONS.**

THE Second Triennial Meeting of the Congress of American Physicians and Surgeons has been held in Washington, during four days of the present week. The morning hours of these days were devoted to the meetings of the component associations and societies, and the afternoon hours to the development and discussion of three selected subjects by the Congress as a body.

There are now fourteen component associations and societies, varying in individual membership from about one hundred to about fifteen. The total membership is about six hundred. Of this number, five hundred and thirty-three were registered, and five hundred were in actual attendance. Sixteen gentlemen from Great Britain and the Continent, of distinction in their various departments of medical and surgical science, were present as guests: Sir William MacCormac, William M. Ord, Thomas Bryant, Reginald Southey, Reginald Harrison, Howard Marsh, Arthur E. Durham, W. W. Ord, all of London; W. T. Gairdner, Glasgow; John Battey Tuke, Edinburgh; John Chiene, Edinburgh; D. J. Cunningham, Dublin; F. H. Haynes, Leamington; Dr. Hoffa, Würzburg; Dr. Florian Beely, Berlin; Dr. Ryerson, Toronto, Canada.

The Congress was in most respects an unqualified success. There were two drawbacks, however, one avoidable and the other possibly unavoidable. The hall for the general meetings, in the Grand Army Building, was poorly adapted to its purpose. The acoustics were bad, and the result was trying, both to speaker and hearer, in fact, the word hearer is scarcely appropriate; it should be rather the one who desired to hear. The weather was a particularly fine specimen of the kind which seems to be reserved for similar meetings if held in Washington in June or September. The first two and a half days were hot in a way which makes activity of any sort a weariness to the flesh and the spirit, but predisposes to the active

formation of ptomaines in the intestinal tract. It was hardly a sufficient comfort to those who had suffered in the same way before to be reminded that the thermometer was in the nineties all over the country, that the children of Minnesota had been cut off from school privileges and that it was just what the corn crop needed.

There are, it is true, many reasons why the time chosen for the meetings of these Triennial Congresses—the fourth week in September—is the best time to have them. The participants have had the leisure of vacations in which to prepare their contributions; they have been refreshed by the vacation's rest; the winter's work has not begun. There are also many strong arguments in favor of the national Capital as the proper place of meeting of a national organization of this kind. All this must be granted. At the same time, experience has shown us that the Capital is apt to welcome meetings at this season with too much meteorological fervor. The air was not only hot, but lifeless. It is difficult, under such circumstances, to keep the attention profitably fixed, and the mind keenly alert—as the programme offered demands—from 10 A. M. to 1.30 P. M., and again from 3 P. M. to 6 P. M., and that for four days. That the very considerable number of participants who were their own patients should exclaim: "Would that the time or place were different!" is not to be wondered at. The physiologists, who probably do not desire to interest themselves in pathological processes, expressed their feelings in the form of resolutions—resolutions in which the gynecologists refused to join; although by Thursday night, but six out of forty or fifty of these specialists were left to respond to the last call for dinner.

After all, the greatest good of the Congress is what every one desires most; and the members will doubtless continue to lay their gastro-intestinal tracts upon the altar of the Congress if by such an offering its continued usefulness and vigor can best be secured. But it was suggested that possibly the winter vacation would be a feasible time.

The programmes were perhaps too full, and some of the papers presenting large subjects in varied aspects were too long for discussion. One association offered sixty-seven papers on its programme, and in the general afternoon sessions papers covering an hour of rapid reading were presented. It is to be hoped that the component associations will make their arrangements so as to leave the afternoons free for the general sessions in which all should participate.

In all other ways the Congress was harmonious, satisfactory and successful in a high degree. Its hopes and objects are clearly and concisely stated by Dr. William Pepper, the Chairman of the Executive Committee, in the brief address with which he called the general session to order on the first day.<sup>1</sup> These hopes and objects have been greatly encouraged and forwarded by this second meeting, and this is due, in a large measure, to the zeal and assiduity of the Ex-

<sup>1</sup> See page 316 of the Journal.

ective Committee and the Committee of Arrangements.

Dr. S. Weir Mitchell, of Philadelphia, as the graceful and efficient President, delivered an interesting address, which is published at page 309 of this issue. The addresses before the Associations of Physicians and the Orthopedic Association are also published this week, and a beginning of the reports; and the JOURNAL will continue in its next issue the addresses, the reports, and some of the papers presented.

Lest any of our readers should regard the criticisms we have offered as captious, we will sum them up in the one statement, that the programme was too good, and there was too much of it.

### ARE HOSPITALS NECESSARILY NUISANCES?

THERE seems to be a growing tendency to regard hospitals as nuisances, or at least as undesirable neighbors. The Trustees of the Free Hospital for Women not long ago purchased a lot of land in Brookline, with the intention of building a hospital to be devoted entirely to gynecological work. It would seem as if such a building could hardly affect the value of adjacent real estate very unfavorably, but apparently the owners of land and houses in the neighborhood thought otherwise. Some of the objections urged against the granting of a permission to build were unique, others far-fetched and absurd, but they seem to have had weight with the selectmen of the town. The remonstrants forced the friends of the hospitals to admit that when patients were recovering from ether, there was sometimes more or less screaming, and that in warm weather it might be necessary to leave the windows open at that time. The counsel of one of the objectors remarked that the erection of such a hospital would certainly be a detriment to his client's home. There is a prejudice against hospitals, and when it is known that it is a charity hospital the prejudice is still stronger. Another important point is its influence on school-children. They will imagine a great many things, and it is just as bad to have their imagination aroused as it is to see the very worst of sights.

This surely is carrying even sentimental objections pretty far, but the real state of the case seemed to be that such an institution is a hindrance to suburban land that is being "improved for residential purposes."

A somewhat similar case occurred in Winthrop some months ago, except that in this case the hospital had already been built, and had been doing good work for a number of years, and the private houses had grown up around it. Since 1878 the Sea Shore Home had received during the summer months a large number of infants suffering from intestinal diseases, with their mothers. The number of children treated by the institution had amounted to 2,183. Within a few years extensive additions had been made to the buildings. Last winter the citizens of the town, at the annual town meeting, voted that the institution was a nuisance

and that a renewed occupancy of the buildings would be opposed with the assistance of a legal injunction. With this evident intention to make the position an undesirable one, the managers felt that it would be best to remain inactive during the present season, not yielding their position, but retaining the right to carry on a home for sick children when the proper time comes.

Is it well that the unselfish efforts of those who are devoting time and money and skill to the amelioration of the lot of the unfortunate and impecunious sick should be hampered by opposition of this narrow, selfish character?

### MEDICAL NOTES.

ECHOES OF THE WASHINGTON CONGRESS OF PHYSICIANS AND SURGEONS.—It is perplexing to have to decide between a discussion on recurrence of cancer of the breast, one on the relations of arterial disease and visceral changes, and one on the epidemiology of influenza—all at the same time, and all conducted by eminent authorities.

A programme which ranges over all the intervening ground from conditions underlying the infection of wounds, the late manifestations of syphilis and fibroid processes, to pneumonia in children, and from thence to the anatomy of the elephant's ear and the teeth of cheiroptera—is vertiginous.

The only paper offered the Congress from a female source was entitled, "Notes on the Hearts of Certain Animals."

For junketing there was neither time nor inclination.

Wednesday evening, after the address, the Congress was received by its President, Dr. Mitchell. Thursday afternoon the Congress was received informally by the President of the United States, at the White House.

The Surgical Association and the Association of American Physicians, with their invited guests, dined together Thursday evening, at the Arlington Hotel. About two hundred sat down to table, and Dr. J. S. Billings presided. He did not spare the invited guests, every one of whom was called to his feet. The expressions of pleasure and satisfaction with their American experiences were gratifying, as they were warm and evidently spontaneous.

The Pediatric Society was entertained by its President, Dr. Rotch, at breakfast, Wednesday morning. This Association, and many of the others, had separate dinners Thursday evening.

The Dermatological and the Association of Andrology and Syphilology dined together, Tuesday evening.

Private dinners were given by the President, Dr. Mitchell, by the Chairman of the Executive Committee, Dr. Pepper, and by Dr. J. S. Billings, of the Committee of Arrangements.

THE AMERICAN MICROSCOPICAL SOCIETY.—The American Microscopical Society held its fourteenth

annual meeting in Washington, August 10-14. Dr. John S. Billings made an address of welcome, and spoke at some length of the microscopic work that was done at Washington in the scientific offices of the Government, by the local society, in the Army Medical Museum, and particularly of that of the late Dr. J. J. Woodward. The use of the microscope in Government work was further discussed by Dr. J. Melvin Lamb. A committee was appointed to consider the feasibility of inducing American manufacturers to make their instruments of the same standard. A proposed new constitution was considered, and the society decided that it would call itself in the future, the American Microscopical Society instead of the American Society of Microscopists.

**CHOLERA** is reported to be making serious advances in Syria. It has reached Aintab on the highway to Aleppo, and its rapid extension is believed to be associated with the immigration of destitute Russian Jews. The disease has fortunately disappeared from the Hedjaz. Cholera has also broken out amongst Chinese coolies on board a steamer bound for Singapore, and a few cases resulted in Singapore itself.

**LEPROSY IN ST. KITTS.**—A petition to the Queen has reached the British foreign office from the island of St. Kitts, in the West Indies, referring to the rapid increase of leprosy on the island, and praying that an order may be issued for the compulsory seclusion of all victims of the disease.

#### BOSTON AND NEW ENGLAND.

**FOOD AND HEALTH EXPOSITION.**—An exhibition, under the auspices of the Boston Retail Grocers Association, will be opened in the Mechanics Building, on October 5th, and will continue three weeks. The object is to give a practical exposition of the art of cooking, and of the right ways to select wholesome food.

**DR. ALBERT HOFFA**, of Würzburg, operated at the Children's Hospital in Boston, on Wednesday, September 16th, upon a young girl with a congenital misplacement of the hip. He performed his operation, which consists of exposing the neck of the femur, by Langenbeck's incision for excision of the hip, freeing the capsule thoroughly, severing the round ligament, deepening the acetabulum and replacing the head of the bone in its normal socket. The case is doing well at latest accounts.

**HYDROPHOBIA IN SALEM.**—On September 9th a patient was admitted to the Salem Hospital with hydrophobia, from the effect of which he died. He had been bitten by a mad dog on July 3d. Within forty-eight hours a grandson of the patient, who had been bitten by the same dog at about the same time, died of hydrophobia.

#### NEW YORK.

**THE DEPARTMENT OF STREET-CLEANING.**—Mayor Grant, with the official approval of the Board of Health,

as required by law, has removed from office Commissioner Heattie, the head of the Department of Street-Cleaning; a measure which the mayor, in his communication to the Health Board, certified was in his judgment required in the public interest. This action of the mayor was in great part the result of a statement presented to him by President Wilson, of the Health Department, in which attention was called to reports of the regular monthly inspection of the streets for August, of a special inspection made on the 14th by sanitary officers of the Department, and of the report of Dr. Moreau Morris, Chief Inspector in charge of the Summer Corps of Physicians. The communication concluded as follows: "Cleanliness of the streets is regarded by this Department as very important to the public health, and it is apparent from the reports above referred to that their condition is far from satisfactory in this particular, and that this subject, for sanitary reasons, demands special attention." The mayor has appointed to the position thus vacated Mr. Thomas S. Brennan, a gentleman who has had a very large experience in connection with the charitable and criminal institutions of the city. After having served as Steward and Deputy Warden of Charity Hospital on Blackwell's Island, he was appointed, in 1866, Warden of Bellevue Hospital, a position which he held until 1875, when he was made one of the Commissioners of Charities and Correction. He served in this capacity for nearly fifteen years.

**THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS** held its fourth annual meeting at the building of the New York Academy of Medicine, on September 17th, 18th and 19th, and a considerable number of physicians from various parts of the country attended the sessions. On the opening day an address of welcome was delivered by Dr. D. B. St. John Roosa, of New York, and in the evening a banquet was enjoyed by the members and a number of invited guests.

**YALOO, THE DOUBLE-BODIED HINDOO LAD.**—Dr. George Bleything, having examined the double-bodied Hindoo lad recently brought to this country, has made the following report in regard to him: "I find him to be a remarkable case of arrested development in fetal life. The boy himself is a fine, bright, well-developed youth of eighteen years, and attached to the extremity of his sternum is the incomplete body of a twin. The arms are given out from the attachment to the sternum of the young man, without scapula. The trunk is short and incomplete, but terminates in a pelvis, with which the legs are connected. There would seem to be no separate heart in the parasite, and the pulse, both radial and axillary, is synchronous with that of the autosite. There is anchylosis of the joints in the undeveloped child. The young man is conscious of a sensation when this second body is roughly touched." The parasitic growth appears to give him very little inconvenience, and he is very agile in his movements.

## Miscellany.

### EFFECTS OF VENTILATION ON MICRO-ORGANISMS.

DR. RICHARD STERN<sup>1</sup> has made experiments on this subject in a room in which he could have quiet air, or a more or less complete ventilation. The openings in the walls of the room were so arranged that he could admit the air from without either at the upper part near the ceiling and convey it off near the floor on the opposite side of the room (winter ventilation), or the air could be admitted near the floor and conducted out on the opposite side of the room near the ceiling (summer ventilation). The rapidity of the ventilation was also under complete control. The air of the room was intentionally loaded with micro-organisms. Pure cultures were mixed with the dust collected from school-rooms and factories. This was then dried and pulverized and blown about the room. The air was then examined for the number of micro-organisms, by Petri's method at various times. The conclusions arrived at were: (1) That the micro-organisms rapidly sink to the floor in quiet air. The finer the dust upon which the micro-organisms rest the slower the gravitation. (2) The usual ventilation, effecting a renewal of air from one to three times an hour, has no effect upon the removal of micro-organisms with summer ventilation, and only to a very limited extent with winter ventilation. (3) Ventilation, effecting a more rapid renewal of air (six or seven times to the hour), effects the removal of micro-organisms, but slightly without a sensible draught. (4) A rapid and complete removal of the micro-organisms from the air is only attainable with a strong draught. (5) Micro-organisms are not blown off from the floor, walls, furniture, clothing, etc., even with the stronger draughts. (6) The evolution of steam in a room is not capable of rapidly and completely precipitating the micro-organisms, although it hastens this process to an appreciable extent.

## Correspondence.

[From our Special Correspondent.]

### SEVENTH INTERNATIONAL CONGRESS OF HYGIENE AND DEMOGRAPHY.

MEETING AT LONDON.

(Continued from No. 12, page 307.)

REGULATION OF THE MILK SUPPLY. — SEWAGE. — SANITARY ARCHITECTURE. SELF-PURIFICATION OF RIVERS. CREMATION. COMPULSORY NOTIFICATION OF INFECTIOUS DISEASES. — FISHER MARKS AS A MEANS OF IDENTIFICATION.

LONDON, August 21, 1891.

IN the Section upon Relation of Animal Diseases to Man, the discussion was in nearly the same line as that of the former Section. Dr. Ostertag's paper was on "Regulation of the Milk Supply, with Reference to Diseases Transmissible by Milk." He believed that the following requirements were essential to prevent danger from the consumption of milk: (1) That all dairy farms be licensed; (2) that all animals kept for milking be examined by a veterinary surgeon from time to time; (3) that the owners of dairy farms be bound to provide only good undamaged fodder; further, to give immediate notice of the illness of

Sandbarn, from *Zeitschrift für Hygiene*.

any milch cow to the attending veterinary surgeon, and, until he gives leave, not to send the milk of the diseased animal to market; (4) that the business of milking be performed with the most punctilious cleanliness, and that no person suffering from any infectious illness be employed to milk; (5) that the mixed milk obtained by milking be cooled and stored in special rooms, not in living or sleeping rooms; (6) that it be transported only in suitable vessels; (7) that during the prevalence of aphthæ only boiled milk be brought into the market, whilst all milk which must be considered nauseous or injurious be excluded from the provision market. Likewise, at the outbreak of any epidemic in a house where dairy farming is carried on, the sale of milk be forbidden; (8) in obtaining the so-called "milk for children," especially strict regulations must be carried out as to the feeding of cows, cleanliness in milking, and the cooling and mode of transportation to market. The time in the Section upon Infancy and Childhood was chiefly occupied with papers and discussions relative to "Neglected Children in Towns and Cities," and "Free Dinners for School Children."

In the Section upon Chemistry and Physics, Dr. Thresh read a paper on the "Chemical and Physical Processes Employed in the Treatment of Sewage." Dr. Carpenter treated of the "Duty of a Locality to Utilize the Nitrogenous Matter in Sewage for the Benefit of the Nation"; he also read a second paper on "The Power of the Soil and Vegetation Combined to Destroy Disease Germs and so Prevent the Possibility of the Spread of Entheitic Disease in Consequence of Sewage Farming."

In the Section on Architecture some excellent ideas were presented in a paper entitled "Some Insanitary Superstitions in House-building." It attacked the method of constructing houses (everywhere prevalent in America) with many air-spaces for the accumulation of dirt and dust between the ceilings, the floors and outer walls. Further papers were read on the Sanitation of Theatres.

In the Engineering Section, Dr. Percy Frankland presented the subject of our "Present Knowledge as to the Self-Purification of Rivers." His conclusions were that the evidence of such purification is wholly inadequate to justify the use of polluted river-water at points below the source of pollution. Other valuable papers were presented on Refuse-Burning and Street-Cleaning. Mr. Jones's paper on the "Refuse Destructor at Ealing" was followed by a visit to the works at that place in the suburbs of London. The process here is combined with the chemical precipitation of sewage. The sludge which is deposited from the sewage being burned together with the garbage collected in the town.

One of the most interesting topics of the third day was the discussion upon Cremation, in the Section on State Hygiene, between Sir Henry Thompson, in favor, and Mr. Seymour Haden, against the practice.

The former claimed the following advantages in support of cremation:

(1) A diseased dead body is rendered incapable of communicating any malarial to the living.

(2) The assignment of large and desirable tracts of land throughout the country for the imperfect and sometimes hazardous process of purification by burial in earth is rendered needless. Every acre hitherto thus devoted may in process of time be made free for the production of food; or, in thickly populated neighborhoods, as open spaces for exercise and recreation, may be set apart forever to promote and maintain the public health.

Mr. Haden presented the following propositions:

(1) That the natural destination of all organized bodies that have lived, and that die on the earth's surface, is the earth.

(2) That the evils, which certain theorists would have us believe to be inseparable from the principle of interment, are independent of that principle and of our own creation.

(3) That the source of these evils is to be found, not in the burial of the dead, but in the unreasoning sentiment which prompts us to keep them unburied as long as possi-

ble, and then to bury them in such a way that the earth can have no access to them.

(4) That the principle of burial supposes the resolution of the body by the agency of the earth to which we commit it, and that the earth is competent to effect that resolution, and to effect it innocuously.

(5) That to seek to prevent the beneficent agency of the earth by inclosing the dead in imperishable coffins, brick graves and vaults is in the highest degree irrational, since it engages us in a vain resistance to an inevitable dispensation, and has led us to accumulate in our midst a vast store of human remains in every stage and condition of decay.

(6) That the remedy for such evils is not in cremation, but in a sensible recognition of, and a timely submission to, a well-defined law of nature, and by legislative action to enforce the provisions of that law.

In the discussion which followed, Sir Spencer Wells advocated cremation, and very many took part in the discussion.

In the General Division upon Demography the time was occupied with papers on "India Factory Legislation," "Home Work in Russia," and the "Influence of the Age of Parents on the Vitality of their Children."

The principal work of the Congress practically ended with the sessions of Friday, although the closing meeting was not held till Monday, August 17th.

The attendance on Friday was fully as large as upon any day, the interest in the papers and discussions being kept up till the close. Among the most important papers on that day were one upon "The Improved Hygienic Condition of Maternity Hospitals," in the Section on Preventive Medicine, by Dr. Priestley; and others upon "The Bacteriological Examination of Drinking-water," and upon "Disinfectants," in the Section upon Bacteriology.

In the Section on Diseases of Animals, Dr. Crookshank contributed a paper on "Actinomycosis," which was followed by an interesting discussion by Drs. Ponfick, Nocard, Salmon and others.

The subject of "Block-dwellings for the Working-classes," was presented in the Section on Architecture in its Relation to Hygiene, by Dr. Sykes, in a carefully prepared paper illustrated with diagrams.

Very much interest centred in the discussion in the Section upon State Hygiene, relative to the Compulsory Notification of Infectious Diseases. The new law upon this subject has been vigorously opposed by a very large proportion of the medical profession in England, but the law is gaining ground yearly, and the number of districts which have adopted it is constantly increasing.

Mr. D. Biddle, M.R.C.S., read a paper upon the subject entitled "Should Compulsory Notification be made General?" in which he took the negative side of the question, and adduced a series of tables compiled from the Registrar General's returns in support of his position.

Dr. P. Boobyer, of Nottingham, presented the opposite view of the subject, and strongly favored the practice. He gave the history of compulsory notification before the Act of 1889; it was in force under local Acts in fifty-nine British towns previous to that year; but in only a small proportion of the towns have all the diseases now on the schedules been included from the outset. He then discussed the theory of various forms and methods of notification tried in different urban districts, the system introduced by the Act of 1889 (dual notification), and the relative merits and demerits of the so-called single and dual systems. Householder notification was necessarily unsatisfactory. He proceeded to the enumeration of the more prominent advantages to be derived from compulsory notification in all places where the sanitary authorities are alive to their obligations and able to enforce the necessary preventive measures. Both with respect to diseases dependent for their propagation upon personal contagion, and to those arising in connection with insanitary conditions, notification simply imparted to the sanitary authorities the information necessary to enable them to exercise those powers with which the earlier Public Health Acts

had already invested them. Compulsory notification, and even isolation, were the necessary outcome of evolution as applied to preventive medicine. Allusion was made to the attempt that had been made of late years to discredit notification by the manipulation of statistics, and to some of the errors into which the critics had fallen. Apart from actual error in method or treatment, there were sources of fallacy in the very nature and history of epidemic diseases which rendered the reliable application of statistics to a study of the causes underlying variations in their prevalence and fatality a matter of extreme difficulty. In conclusion, he urged the general application of the system of notification.

That the audience was largely in favor of the views of Dr. Boobyer was very evident, not only from the discussion which followed, but from the resolutions in favor of compulsory notification, which were carried by a large majority, only five voting against them.

Several interesting papers were read in the General Division on Demography, among which may specially be named that of the President, Mr. Francis Galton upon "Finger-marks as a Means of Personal Identification." Mr. Galton showed the degree of facility by which it is possible to determine whether the duplicate of a submitted set of impressions is or is not contained in a catalogued collection of the finger-prints of different persons, say of criminals. The prints used were those of the bulls of the ten digits, in each of which a pattern is to be found that is usually isolated by one or two pairs of divergent papillary ridges. The varieties of these patterns, and the method of their formation, were described by him in the Philosophical Transactions of the Royal Society, 1891, where evidence was also given of the persistence, throughout life, in the minutest details of the ridges by which they are formed. In mere size the patterns grow with the individual, and in their proportions they will somewhat vary according to the fatness or leanness, etc., of the finger, but their general character, on the one hand, and their structure in all its minuteness on the other, remains unchanged.

The method consists of two stages: The first is classification according to the general character of the pattern, the second is the scrutiny of all the specimens that are contained in the same class by attending to one or more of the minutiae. For classification, the method is adopted of regarding only the most obvious differences of character in each of the ten fingers; these are whether the pattern in each of them ranks as a "primary," a "whorl," or as a "loop." No other heads are recognized; the few doubtful cases being classed under one or other of these three heads according to a collection of standard specimens. Every one of these classes is, however, liable to a two-fold subdivision.

There is not space to mention in detail the very many excursions and receptions which were kindly tendered to the Congress, the reception by Her Majesty, the Queen, the various garden parties, the trip to Barking and the lunch on board the *Drummond Castle*, also the special meetings of the Section upon Sanitary Progress in India.

The meetings were brought to a successful close, after a round week of work, by a general meeting in the University of London, on the 17th of August, at which it was voted to accept the invitation of the authorities of Budapesth (Hungary) to meet in that city in 1894.

OUT-DOOR GAMES IN GERMANY. — A course of instruction in out-door games will soon be opened for teachers in Berlin. This is an omen of a better time coming for young people in Germany, where the more or less complete absence of out-door games for young and old is a sad feature in the life of the people. The Emperor is enthusiastically in favor of a change in this direction, and plays football himself with his own sons and Prince Henry at the new palace near Potsdam.

## RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, SEPTEMBER 12, 1891.

Cities.	Estimated population for 1890.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from					
				Infectious diseases.	Consumption.	Diarrheal diseases.	Typhoid fever.	Diphtheria and croup.	
New York	1,515,301	747	241	24.57	13.26	11.46	1.47	4.03	
Chicago	1,046,941	412	207	30.48	8.16	11.40	7.92	4.80

Hyde Park	10,193	4	1	—	25.00	—	—	—	
Peabody	10,158	4	1	25.00	—	25.00	—	—	

Deaths reported 2,807; under five years of age 1,225; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 716; consumption 287, acute lung diseases 172, diarrheal diseases 114, diphtheria and croup 104, typhoid fever 19, scarlet fever 34, whooping-cough 27, cerebro-spinal meningitis 18, malarial fever 12, measles 8, erysipelas 4, typhus fever (Philadelphia) 1.

From scarlet fever New York 17, Chicago and Pittsburgh 4 each, Philadelphia and Brooklyn 3 each, Cincinnati, Cambridge and Lawrence 1 each. From whooping-cough Philadelphia 9, New York 5, Chicago and Milwaukee 3 each, Boston and Pittsburgh 2 each, Brooklyn, Washington and Charleston 1 each. From cerebro-spinal meningitis New York 6, Chicago 4, Worcester and Fall River 2 each, Philadelphia, Brooklyn, Nashville and Lynn 1 each. From malarial fever New York 6, Brooklyn 3, Charleston 2, Nashville 1. From measles Chicago 2, New York, Philadelphia, Brooklyn, Boston, Milwaukee and Washington 1 each. From erysipelas New York 2, Chicago and Brooklyn 1 each.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,405,408, for the week ending September 5th, the death-rate was 16.8. Deaths reported 4,038; acute diseases of the respiratory organs (London) 155, diarrhoea 202, whooping-cough 64, fever 34, diphtheria 31, scarlet fever 27, measles 21.

The death-rates ranged from 11.3 in Nottingham to 27.5 in Preston, Birmingham 15.7, Bradford 15.4, Hull 17.4, Leeds 17.4, Leicester 17.9, Liverpool 21.2, London 16.0, Manchester 16.1, Newcastle-on-Tyne 30.5, Sheffield 17.2, Sunderland 20.3. In Edinburgh 16.3, Glasgow 19.5, Dublin 18.5.

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 12, 1891 TO SEPTEMBER 18, 1891.

A list of all officers granted Surgeon DAVID L. HASTINGTON, U. S. A., extended to include September 30, 1891.

The retirement from active service of Colonel EDWARD P. VORLES, chief medical purveyor, U. S. A., is announced. S. O. 211 A. G. O., September 11, 1891, Washington, D. C.

Major CHARLES E. HOLMANN, U. S. A., is relieved from duty at Fort Clark, Tex., and ordered to Fort Douglas, Utah,

relieving Surgeon WILLIAM D. WOLVERTON, U. S. A., who, upon being relieved, will proceed to Fort Schuyler, N. Y., and report for duty at that station.

Assistant Surgeon GEO. M. WELLS, U. S. A., relieved from duty at Columbus Barracks, O., and ordered to Fort Thomas, Ky., for temporary duty, relieving Assistant Surgeon Henry L. RAYMOND, U. S. A., Assistant Surgeon Raymond, on being relieved, will report to the commanding officer, Fort Robinson, Neb., for duty at that station.

Assistant Surgeon LOUIS W. CHAMPTON, U. S. A., is relieved from duty at Fort Sheridan, Ill., and ordered for duty at Fort Townsend, Wash., relieving Assistant Surgeon JAMES C. WORTHINGTON, U. S. A., Assistant Surgeon Worthington, on being relieved, is ordered to Fort Thomas, Ky., for duty at that station, relieving Assistant Surgeon GEO. M. WELLS, U. S. A., Assistant Surgeon Wells, on being relieved from temporary duty at Fort Thomas, Ky., is ordered to San Carlos, Ariz., for duty.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING SEPTEMBER 19, 1891.

A. A. HOCHLING, medical inspector, ordered as member of Medical Examining Board.

G. E. H. HARMON, surgeon, ordered to the U. S. S. "Yorktown," and granted leave.

JNO. C. BOYD, surgeon, detached from the U. S. S. "Yorktown," and granted leave.

F. L. DuBORS, medical director, detached from Navy Yard, Portsmouth, N. H., and wait orders.

J. G. AYRES, surgeon, detached from U. S. S. "Wabash," and to Navy Yard, Portsmouth, N. H.

F. J. B. CORDEIRO, passed assistant surgeon, ordered to the U. S. S. "Wabash."

O. D. NORTON, passed assistant surgeon, ordered to the U. S. S. "Petrel."

E. H. MARSTELLER, passed assistant surgeon, detached from U. S. S. "Petrel," and granted leave.

JNO. H. HALL, surgeon, ordered to appear before Retiring Board.

## RECENT DEATHS.

HENRY DYER, M.D., M.M.S.S., died in New York, September 21st, aged eighty-seven. He graduated from Harvard College in the Class of 1826, and from the Medical School in 1829. He practiced medicine in Boston for over thirty-five years. Twenty years ago he gave up active practice, and went to New York, where he has since lived.

JAMES WATT, M.D., of Brooklyn, died September 11th, aged forty-seven. For some years he was registrar of vital statistics of the Brooklyn Board of Health, and was one of the first in this country to publish a weekly bulletin of vital data for the use of the profession and sanitary officials.

## BOOKS AND PAMPHLETS RECEIVED.

Corability of Consumption. By Charles W. Dulles, M.D. Reprint. 1891.

The Annual Statistics of Manufacturers. 1890. Boston: Public Document No. 15.

Enucleation of the Eyeball. When and How to Operate? By J. Hober Egbert, A.M., M.D., Ph.D. 1891.

Evidence of Arsenical Poisoning in the Snook-Herr Wedding Guests. By J. W. Irwin, M.D. Reprint. 1891.

Influence of Heredity in Producing Disease and Degeneracy. The Kennedy. By Gonzalva C. Smythe, A.M., M.D. Reprint. 1891.

Syllabus of the Obstetrical Lectures in the University of Pennsylvania. By Richard C. Norris, M.D. Second edition, Philadelphia: W. B. Saunders. 1891.

Tables for Doctor and Druggist. Compiled by Eli H. Long, M.D., Professor of Materia Medica, Buffalo College of Pharmacy, etc. Detroit: George S. Davis. 1891.

Three Thousand Questions on Medical Subjects. Arranged for self-examination, with the proper references to standard works. Philadelphia: F. Mackintosh, Son & Co. 1891.

Pocket Medical Dictionary, for the use of Students of Medicine. By Ch. Gatehell, M.D., Professor in the University of Michigan. Chicago: Era Publishing Company. 1891.

Therapeutics, Its Principles and Practice. By H. C. Wood, M.D., F.R.C.S. The eighth edition of a Treatise on Therapeutics, rearranged, rewritten and enlarged. Philadelphia: J. B. Lippincott Company. 1891.

## Addresses.

### THE PRESIDENT'S ADDRESS

AT THE OPENING OF THE TWELFTH ANNUAL MEETING OF THE AMERICAN SURGICAL ASSOCIATION, WASHINGTON, SEPTEMBER 22, 1891.

BY CLAUDIUS H. MASTIN, M.D., OF MOBILE, ALA.

**FELLOWS OF THE AMERICAN SURGICAL ASSOCIATION:**—At your last meeting in May, 1890, you selected me to be your presiding officer at this session: a session of especial interest, because it is the occasion when the several special associations conjointly assemble to constitute the Congress of American Physicians and Surgeons.

Thoroughly appreciating the importance of the trust and acknowledging the very great honor you have done me, I embrace the first opportunity which has presented, to thank you for this generous manifestation of your confidence and esteem.

It now becomes my pleasing duty to welcome you, together with our distinguished confères from abroad who have honored us with their presence, to this, the beautiful Capital city of this great, growing and prosperous republic; a city surpassing in beauty and rivaling in grandeur the older and more favored capitals of the old world; noted both at home and abroad for its intellectual and scientific advances, it is to become in the not distant future the centre of the science, the literature and the arts of the Western hemisphere; as it is, even now, the political pivot around which revolves more than sixty millions of freemen! It is here that the Congress of American Physicians and Surgeons holds its triennial sessions, and it is the home of this Association. It is to this and to these that I bid you a thrice hearty welcome!

Since the organization of this Association, a body having for its object the advancement of the science and the art of surgery, a decade has passed away, and with the opening of this session a new epoch in the history of the American Surgical Association begins. It, therefore, is a fitting time to take a retrospective view of our history, to congratulate ourselves upon the auspicious present, and linger for a moment in the contemplation of the future. This I conceive to be a more appropriate theme for the occasion, than for me to weary your patience with a scientific dissertation, especially so since the efficient Committee charged with the preparation of the programme has laid before you a feast rich in this particular.

It was in May, 1879, during the meeting of the American Medical Association, then in session at Atlanta, Georgia, that the founder of this Association called around him a few selected friends, and disclosed to them a plan—which for many years had been a cherished object of his ambition—that of organizing an association which should bear a national name, and embody in one harmonious whole the surgical talent, experience and wisdom of this great country. The question was pertinently asked, "What need is there of such an organization since the country is full of all kinds of medical societies?" It was argued that the surgical section of the American Medical Association offered all the requirements necessary, and that the organization of a special association having for its object the advancement of the science and art of surgery was not called for, and would be looked upon as hav-

ing for its purpose only the injury of the old Association. Striking, as it were, a direct blow at the surgical section.

With the far-seeing wisdom characteristic of the man, he thought differently, and believed the effect would be directly the opposite. He believed, and said, that the time had come in the history of medical and surgical affairs in America, when such an organization was a necessity, and should be created. He disclaimed then, as we do now, any opposition whatever to the old Association; and he asserted that it was impossible for any new organization to be in the least detrimental to it.

From the day on which the old Association was organized he had been an active and influential member,—once its president, often a contributor to its volume of transactions. Governed by its code of ethics, he remained true and loyal to all its requirements, as evidenced by the fact that when on his death-bed he was asked by a friend what message he desired to send to the American Medical Association, he replied, "Give them my love!" Also, the very last paper he ever wrote was being read in that Association during its session of 1884, on the same day that he died.

It is my honest conviction that neither our illustrious founder, nor any fellow of this Association, has ever entertained any sentiments of opposition to the old Association. On the contrary, as American physicians and surgeons, we feel an honest pride in the work that it has done; and we are the last who would obstruct the progress of an association which is so necessary to the professional interests of the country at large. We are free to admit, however, that we know the time has come in the history of medical affairs in this country when the special branches of the profession must be separately recognized: not that they should be divided into departments having no reliance one upon another, but as integral parts of a great and undivided profession. They should be so organized as to stand "distinct as the billows, yet one as the sea." The Congress of American Physicians and Surgeons is simply a development of this principle!

But he was building even better than he knew. And now, the ten years which have passed so rapidly away have answered the question—"What need is there of such an organization?" The first regular meeting of this Association, held for the transaction of scientific and practical work, took place at Coney Island, in the State of New York, in the September of 1881—a meeting which was attended by a very small number of its fellows, yet the character of the work which was done was useful, and laid the foundation of the triumphant success which has since been attained.

Nomadic in its beginning, the next meeting was in the city of Philadelphia, on the thirty-first of May, and the first and second days of June in the year 1882. At this session a fellowship of only twenty-five were present; but the work was practical, full of zeal, and showed that the Association was to become in the not distant future an altar upon which would annually be laid valuable contributions to surgical science; and the world said even at that time, its membership was destined soon to become earnest and zealous laborers in the interest of human progress and human suffering.

The third session was called together in the city of Cincinnati, on the thirty-first of May, 1883, and forty fellows all told constituted its full strength. Its first

volume of transactions, which was published after that meeting, attests the amount and the value of the work which was accomplished. Everything then seemed to foreshadow a bright future, and nothing transpired to dim the occasion save the absolute refusal of our beloved founder and president to accept a re-election to office.

That great man, the Nestor of modern American surgery, the founder of, and the cherished idol of this Association, Samuel David Gross, standing without fear and without reproach, held that he had no pre-emption right to office, and contended that he had occupied it long enough. He thought that his re-election would be at variance with the genius of our republican institutions and the habits of the American people. He believed that rotation in office should be the order of the day, not only among politicians but among scientists and professional men. He felt that his highest ambition, as respected this Association, had been accomplished. He appreciated clearly that the work which he began was exceeding his most sanguine expectations and was surely destined to pass into history. We knew that we were losing the guiding hand of a great pilot, and we were loath to permit him to leave the helm of office to serve in the ranks. In the language of a gifted fellow of this Association, "Had the constitution conferred upon us the power, we would have put on him the royal purple, and hailing him chief among all, have bid him wear it for life." But he was inflexible, and that meeting was the last he ever attended. Those of us who were present on the closing day of that session can never forget the trembling words and tearful eyes when he said: "Now that I am about to retire from the discharge of these duties, I feel sure that the interests of the Association will be perfectly safe in your hands, and in the hands of my distinguished successor. I have no greater ambition than to live in your affection and esteem, and to witness the ever-increasing prosperity of this Association; its success is closely associated with the remainder of my life. I believe that we have an association which is destined to become a power for good in the land; and when I am dead and gone, you will not, I am sure, relax in your efforts to make it what its founder intended it should be—a great and lasting institution. God bless you, gentlemen, in all the relations of life and may you ever be faithful to the interests of the profession and the code of ethics in connection with which we have carried on our work."

Gentlemen, these were the farewell words of an old patriarch to his children, and they should sink deep into your memories; for they were spoken by a truly great man, one of those who are "born beneath the aspect of a bright-eyed star, and whose triumphant adamant of soul is but the fixed persuasion of success." No less than one short year from that day he rounded up his great life, and rested.

The future was before us, when from Cincinnati the Association took a new departure; and under the leadership of that venerable and gifted surgeon, Edward Mott Moore, we next assembled here in the city of Washington on the thirtieth day of April, 1881. From that time it can truly be said, "we have had a local habitation and a name." Time does not permit me to enter into the details of our annual sessions which have been held in the city each spring, nor to mention the interest and enthusiasm of our fellows

which have made these reunions so pleasant and instructive as they have been. Suffice it to say, our successive and successful meetings from then till now, under the guiding hands of Moore and Briggs, and Gunn and McGuire, Agnew, Cheever and Yandell, have gradually passed from small beginnings to the present prosperous and renowned Association which has assembled here to-day.

When this Association was first organized, anaesthesia had but enlarged the domain of surgery; to-day antiseptics followed by asepsis have emboldened the surgeon to undertake and perform operations hitherto deemed impossible. Whilst anaesthesia had measurably lessened shock, antiseptics and asepsis have gone a step beyond, and done much toward the prevention of septic results, thus making the possibilities of surgery even greater.

In the last decade, the rapid and steady advances of the chirurgic art have far outstripped all other departments of the profession; and with the constant and seemingly never-ending improvements now going on in all the branches,—the discoveries in chemistry, with the consequent additions to our *materia medica*; the revelations by the microscope, leading to a proper understanding of pathological lesions, and the clearing up of doubtful points in physiology, together with many new precisions in the study of all the branches of medicine,—have enlarged the vista before us, so that no one can predict the limitations which may not be reached in the next ten years. It was but yesterday when the closed cavities of the body were held as sacred. The organs within the abdomen, the lungs and heart within the thorax, the brain and spinal cord cased by the skull and vertebral column, were each surrounded by a dead-line which none dared to cross. To-day, they have each become the legitimate field into which the surgeon has carried his knife.

The old world and the new world, shoulder to shoulder, have been busily engaged in blazing out the pathway from art to science. If our friends from abroad should ask what has been doing here in America, and what hand this Association has taken in the good work, I could tell them, if it would not be considered invidious for me to use names, what our fellows have been doing in abdominal surgery,—their operations upon all the organs contained in the abdomen, their improvements in the treatment of gunshot and other wounds of the intestines, their work done in the thorax,—and show them that the brilliant achievements of Horsley, Godlee, Macewen and others across the Atlantic, in brain surgery, have been reproduced here with equal success. Even were it proper to do so, time will not permit me to enter into the details of the brilliant work which has been successfully done by the fellows of this Association in all the regions of the body, both external and internal. Suffice it to say, American surgeons have not been idle nor non-progressive, and their work has been placed on record.

Whilst this Association has been advancing the cause of surgery, and doing much to alleviate the distress of suffering humanity, it is sad to have to relate that death has been busy in our ranks, and that some of our best and most eminent fellows, even in the midst of their labors and the height of their usefulness, have fallen in his harvest and been gathered to their fathers. Their loss has proved a serious and irreparable one to the Association no less than to the country.

Since our organization we have been called to mourn

the loss of twenty-one of our brothers, among whom we chronicle the death of two ex-presidents, four ex-vice-presidents, four members of the council and seven of our honorary fellows. Only a very small number have resigned; while, on the other hand, the applications for membership have vastly exceeded the number of admissions.

It is indeed gratifying to know that those who have fallen from our midst were earnest and zealous laborers in the cause of surgery, and enthusiastic in their efforts to advance the best interests of this Association.

Now, when we pause to drop a tear of sympathy and sorrow upon the green sward which covers them, we are solaced with the recollection of their many virtues and the assurance that, although they have passed to the great majority, they had reached eminence in their profession, and left behind them records of well-spent and useful lives. They live honored in our memories.

It is proper to mention that much of the success of this Association has been due to the indefatigable labors of our efficient secretary, who, from the date of our organization to the present time, has been distinguished for the unwearied and unselfish zeal which he has shown in the duties of his office; and he deserves the highest commendation for the work which he has accomplished. No less are we indebted to the recorder of the Association for his labors; for to him especially is due the editing and publication of the beautiful volumes of transactions which have followed our annual meetings. Lastly, though not least, all praise should be accorded to the fellows themselves, for their zealous co-operation in all the labors of our annual sessions, and their successful endeavors to make the Association what its founders intended it should be, a great and lasting institution.

During the ten years which have passed so rapidly away, it will be observed that the Association has steadily advanced in prosperity and usefulness, winning for itself an honorable station among the learned societies of the country, and claiming the admiration of those of the old world. Its volumes of yearly transactions are replete with valuable scientific productions worthy of their authors, and honorable alike to the Association and the nation. Its membership comprises the leading surgical talent of the land, and has fostered an *esprit du corps* such as is to be found only among refined and agreeable gentlemen.

Bound together as we have been for ten years, new acquaintances have been made, and they have ripened into friendships, old ones have been renewed and cemented, and to-day the American Surgical Association stands before the world a united brotherhood inspired with one sentiment, that of doing good to suffering humanity and advancing that department of the healing art to which they have consecrated their lives.

In this connection, a justifiable pride compels me thus publicly to say: From the day of our organization to the present hour, in all our public and private relations, in our intercourse with each other, in our scientific discussions and social reunions, there has not been one single occurrence, one harsh word, to mar the harmony of the occasion or disturb the friendship of its fellows. Verily, this is a record strange and unusual in the history of medical associations, and deserves more than a passing notice.

Such, in brief, is the outline of our past, and whilst we have every cause to congratulate ourselves upon

the successful termination of the decade we are leaving behind, it is still necessary that we should comprehend the importance of the trust which has been placed in our keeping by the founders of the Association. Holding in our hands its spotless record, it is a happy privilege to be able to feel that we desire its history hereafter to be but a just development of that which has gone before; so that the ever-opening pages of its future may continue to be lighted, as they now are, by a bright reflection from its past. Now let us here, to-day join hands around this family altar, and renew our vows to make her still greater than she is.

Before closing, I beg to be permitted to make a few suggestions, which I trust will not be taken in the light of criticism of the past management of the Association: First, I suggest that a business committee be provided, whose duty shall consist in the preparation for and arrangement of the scientific work of the meetings. Such a committee duly authorized would relieve the president and secretary of much labor and responsibility, and the work which they would accomplish would better serve the interests of the Association than if left to the will and pleasure of the presiding officer.

At the session of 1886, a resolution having this end in view was offered as an amendment to the By-laws and under the rule was laid over for one year; it, however, failed to secure the approval of the fellows at the session of 1887, and was finally tabled. I now recommend that proper action be had to the effect that the resolution of 1886 be taken from the table and passed; so that the By-laws will require a committee composed of the president of the Association, its secretary and the recorder, together with the two senior members of the council, to take charge of the preparation of the scientific work of the Association. Their duties should be to select such subjects for the regular essays as they deem best, and have the appointment of those fellows to lead in the discussions of these papers as in their judgment they believe will serve the best interests of the meetings. It should be fully understood, however, that all volunteer papers be left to the option of the fellows without the interference or control of the committee.

Although there has not been as yet any constitutional provision for such a committee, still we have had during the present session and the one immediately preceding it, the benefit of an unofficial committee which has been of vast service in the organization of the meetings, and I now take this opportunity to acknowledge my own indebtedness to them for the very valuable assistance which they have rendered to me in preparing the work of the present session.

Second, I suggest that our present limit of fellowship be increased from one hundred to one hundred and fifty. I am induced to make this suggestion entirely in view of the vast extent of our country, and the large number of young surgeons throughout its wide domain, who are rapidly rising to eminence in their chosen branch. When this Association was first organized, it was then the part of wisdom that our restrictions should be limited, and our membership confined to a small select body of workers. Now the situation is different, and having passed the stage of adolescence we are prepared to extend our field of operations, and in doing so it is but proper that we should remove the obstruction of exclusiveness. With our present limit of membership we are arrogating to

ourselves too much when we claim to be the representative body of American surgeons.

In this I do not desire to be misunderstood, because I would urge that all due vigilance be exercised in the admission of new fellows; the present high standing of the Association must be preserved. Age, scientific attainments, with surgical experience and general culture, should be the necessary prerequisites for admission.

We have set up for ourselves a high standard and we can maintain it only by guarding our portals against unworthy applicants. Besides protecting ourselves, we must remember that each one of the conjoint Association is in honor bound to stand sentinel at the doors of the Congress, and as membership in that body can only be had by virtue of fellowship in one or another of the special societies, it is a duty which each one owes to the other to protect the purity of the confederation.

It should be our aim and attainment to make the Association the representative body of surgical science in America, and to accomplish this most desirable end "genuine ability and solid work must be the indispensable qualifications for admission; and continued scientific activity, the recognized duty of membership." With such a standard before the world, it will soon become a high and coveted honor to be known as a fellow of the American Surgical Association.

Now leaving the larger views I have expressed, for a subject which should be nearer and dearer to us all, though not on that account a narrower sentiment, I ask your indulgence only a few moments longer.

It is well known to the world at large, no less than to the profession of which he was an honored member, that Dr. Samuel David Gross stood first in the foremost rank in his chosen branch of the profession, and that the high position to which American surgery has attained all over the world is largely due to his example and his teachings.

Since he has passed away and his life-work gone into history, we fully appreciate his real worth. And, therefore, it is his friends and admirers who have been inspired to erect a monument to his memory, such a monument as will bear testimony of their gratitude and be in the future an incentive to those who are to come after us to like noble deeds. To further this praiseworthy enterprise, I suggest that a committee from this Association be appointed to confer with the friends and admirers of Dr. Gross and with the medical profession of the whole country to determine the best method to be adopted to secure the requisite amount for the erection of a monument either of marble or of bronze.

Such tributes to the memory of distinguished men are common both in this country and abroad. And when in our own profession a man is found who has done so much to adorn it, it is meet that we should show to the world our appreciation of his work.

Dr. Gross was probably more widely known and appreciated than any American surgeon of recent years, and when we remember that thousands of his pupils scattered throughout the whole of America, men who sat under his teaching and who still retain of him the warmest memories, it is not expecting too much when we feel assured of their cooperation in raising speedily and without dilatory the requisite amount for the completion of such a monument.

I do not suggest that this work be done by the As-

sociation exclusively, nor would I advise it if it could be. I would prefer to see it done by the profession of the entire country, because Dr. Gross belonged to no exclusive faction, but was a member of the profession at large. It is proper, however, that this Association take the initiative in beginning the monument, and I feel assured that there will not be the least doubt as to the successful issue of the undertaking.

If any man in our profession has merited such a tribute, surely Dr. Gross was most eminently entitled to it, for he was a man "animated by fervent attachment to the science and practice of his profession, and it was the duty of his life to augment and exemplify the resources of surgery, and by most assiduous and successful application of his time and his talents, his name has become known and honored, not only in his own country, but in every land."

Appreciated and honored as he has been in life, let us now, since he is dead, build to his memory such a monument as will bear witness in after years to the estimate in which the profession of to-day holds its distinguished members.

If it were asked of me where such a statue should be erected, I would answer, not at Easton, in the State of Pennsylvania, the place of his birth; neither at Cincinnati nor Louisville, where he laid the foundations of his future greatness; nor even in the city of Philadelphia, where that greatness culminated in all its grandeur; but here in the city of Washington, the Capital of the country, which claims him as her own. His name and fame are a sacred heritage to the country at large and to the profession he loved so well. Then, here in this beautiful city, amid these verdant parks, and hard by these massive piles of classic architecture, let us place it. Place it among these statutes, emblems of a nation's gratitude to her illustrious dead, her statesmen, her warriors, her jurists, her philosophers. Build it here, so that in the ages to come, when the youth of the land make their pilgrimages hither, they will behold the monument which their forefathers reared to commemorate the life and character of her greatest surgeon. It will teach them to emulate his example.

Thanking you for your kind attention, we shall now proceed with the regular business of the Association.

#### THE PRESIDENT'S ADDRESS

AT THE OPENING OF THE FIFTEENTH ANNUAL MEETING OF THE AMERICAN ASSOCIATION OF DERMATOLOGY, WASHINGTON, SEPT. 22, 1891.

BY F. B. GREENOUGH, M.D., OF BOSTON.

GENTLEMEN AND FELLOW-MEMBERS OF THE AMERICAN DERMATOLOGICAL ASSOCIATION:—I have the honor to open this, the Fifteenth Annual Meeting of our Association and the second held here in Washington, conjointly with the Association of American Physicians and Surgeons; and it is with great pleasure that I am able to congratulate you on coming together under such auspicious circumstances. Inasmuch as we have a very full and important programme to listen to and discuss, this morning, and as it is, if I may be allowed the expression, our tin-wedding, I have thought it best to vary from the precedent of my predecessors in giving an elaborate address on the subject of the progress of dermatology during

the past year, and instead, give you a brief synopsis of what the Association has done since its start, fifteen years ago.

The American Dermatological Association was conceived in July, 1876, by the following call, which was sent to fifty, more or less, physicians who were known, or supposed, to take a special interest in this subject.

"DEAR SIR:—At an informal meeting of the undersigned, held in Philadelphia, at the rooms of the Section of Practical Medicine of the American Medical Association, on Wednesday, June 7, 1876, after the election of a chairman and secretary, *pro tem*, it was resolved to call upon such American physicians as had evinced a special interest in Dermatology, to unite in forming an American Dermatological Association."

It was also resolved that the meeting for organization should take place on September 6, 1876, at the University of Pennsylvania, Philadelphia, at 6 p. m., or immediately after the close of the meeting of the Section of Dermatology and Syphilology, of the International Congress held on that day. This call was signed by Drs. Bulkley (Secretary *pro tem*) and Fox, of New York; Wigglesworth (Chairman *pro tem*), of Boston; Atkinson, of Baltimore; Yandell, of Louisville; and Duhring, of Philadelphia.

At the meeting called for September 6, 1876, the following gentlemen were present: Drs. Atkinson and Brown, of Baltimore; Bulkley, Heitzman, Keyes, Piffard, Taylor and Weisse, of New York; Duhring and Van Harlingen, of Philadelphia; Bussey, of Washington; Oetelony, of Louisville; and White and Wigglesworth, of Boston; fourteen in all. A Constitution and By-laws were proposed and adopted, and the following officers were elected: President, Dr. White; Vice-Presidents, Drs. Duhring and Taylor; Secretary, Dr. Bulkley; Treasurer, Dr. Hyde. Twenty-three physicians having responded to the call, they, in addition to the six signers of it, in all twenty-nine, were declared to be members of the Association, and the meeting was adjourned to hold its first annual meeting at Niagara Falls, on the first Tuesday of September, 1877. On which date the Association met, with Dr. White in the chair. There were fourteen members present, and fourteen papers were read and discussed, as well as four by title. The President opened the meeting by an address, the title of which was, "A Review of the Progress of Dermatology in America for the past Twenty-five Years, and the Gradual Recognition of the Branch in the Colleges of the Country."

The second annual meeting was held at Saratoga, August 27-29, 1878, Dr. White presiding. Ten members were present, and eleven papers were read.

The third annual meeting was held in New York, in August, 1879, Dr. Duhring in the chair. Thirteen members attended, and the President opened the meeting with an address on "The Rise of American Dermatology." Fifteen papers were read. A feature of this meeting was that on the afternoon of the last day, the Association met at the New York Hospital for a clinical inspection of cases.

The fourth meeting was held at Newport, R. I., August 31 to September 2, 1880, under Dr. Duhring's presidency. Ten members were present, and eight papers were read.

The fifth meeting was held at the same place, August 30 to September 1st, 1881, Dr. Hyde being in the chair. Eight members were present. The President read an address on "Dermatology and its

Relations to Periodical Literature." Ten papers were read. This was the first meeting of the Association at which I had the pleasure of being present, and I never shall forget it. According to the records there were only eight of us present, and we met in a little room up-stairs in the Ocean House, a very different locale from what we have had since, but there was much that was interesting given to us. The subject of Leprosy was quite prominently brought up: Dr. Atkinson reading a paper on "Tubercular Leprosy," Dr. Hyde one on "Acute Tubercular Leprosy," and also one by Dr. H. D. Schmidt, of New Orleans, on the "Pathology of Leprosy." Dr. Atkinson also showed a microscopic specimen of the bacillus of leprosy, which was, I think, one of the first specimens demonstrated on this side of the water.

The sixth meeting was held also at Newport, Dr. Hyde, president, on August 30 to September 1, 1882. Eleven members were present, and four papers were read.

On August 29-31, 1883, the seventh annual meeting was held at Lake George, Dr. Taylor presiding. Thirteen members were present, and seventeen papers were read.

The eighth meeting was at Highland Villa, Highland Falls, near West Point, last of August, 1884, President, Dr. Taylor. Eleven members present, eight papers read.

On the 26th, 27th and 28th of August, 1885, the ninth annual meeting was held at the Indian Harbor Hotel, Greenwich, Conn., Dr. Hardaway, presiding. There were nineteen members present and twenty papers were read. This was a most successful meeting, not only as far as the scientific work went, but the situation was charming and the weather perfect and the members enjoyed their spare hours in rides and walks in the woods and along the shores of the sound.

The tenth annual meeting was held in August, 1886, at the same place, Dr. Wigglesworth as president, opening it with an address. Nine members were present and nineteen papers read. It was at this meeting that the first steps were taken towards the Association joining with other special organizations to form an American Congress of Physicians and Surgeons. The subject was brought up by a motion by Dr. Piffard to the effect that the Association issue a call for an International Dermatological Congress to be held the following year, that is, 1887. The President read a communication, received from Dr. Erving Means, Secretary of the American Surgical Association, with regard to the proposed formation of an association, to be entitled, Congress of American Physicians and Surgeons and to be composed of the various special societies. After discussion it was finally voted, that the incoming officers serve as a committee to carry out these suggestions and to report at the next meeting.

This next meeting, the eleventh, was held in Baltimore in 1887, in the hall of the State Medical and Chirurgical Society, Dr. Piffard in the chair. Seventeen members present, and thirteen papers read. A feature of this meeting was the presence of Dr. Unna, of Hamburg, who, besides taking an interest in the communications and discussions, gave a verbal report on his treatment of leprosy. The council having reported favorably on the suggestions contained in the circular received from the American Surgical Association, the President, Dr. Piffard and the Secretary, Dr. Tilden,

having been present at the meeting held in Washington, September 24, 1886, it was voted that the report be accepted and the incoming President, Dr. Atkinson and the Secretary, Dr. Tilden, were appointed delegate and alternate, respectively, to the executive committee of the Congress.

On September 18-20, 1888, the twelfth annual meeting and first conjoint one, was held at Willard's Hotel, Washington, Dr. Atkinson presiding. Eighteen members were present, and sixteen papers were read, besides the President's opening address.

The thirteenth meeting was held in Boston, in the hall of the Medical Library Association, in September, 1889, Dr. Graham, president, who read an address, after which seventeen papers were read and discussed. A case of prurigo was shown, and called forth a very interesting discussion.

Last year, in the early part of September, the fourteenth meeting took place under the presidency of Dr. Morrow, at the new Bath-House, Richfield Springs. Sixteen members attended, and, after the President's address, fourteen papers were read. The meeting was a very successful one, the members having enjoyed the natural advantages of the place, and been interested in the communication made by Dr. Ransom (director of baths) on the subject of the use of the water in skin diseases. The Association adjourned, to meet in Washington in September, 1891, in conjoint session with the American Association of Physicians and Surgeons.

Such, gentlemen, is the record of our meetings during the past fifteen years, condensed as much as I have been able to do it. In looking over these records, there are many points that are interesting and instructive, but I will only detain you to refer to one. The Association started with a nominal membership of twenty-nine. Some of these members never qualified, others have resigned and dropped out; but to-day, or rather at the time the Transactions for 1890 were published, our membership was thirty-four. This means that we have had the honor and pleasure of having new members join us, who are interested in the same subject that we are. A most superficial running over of our records cannot fail to draw one's attention to the fact, that during the past fifteen years certain names appear constantly as attending, reading papers, and in discussions, and certainly all honor should be given to them for the interest they have taken in our Association and the work they have done. But, gentlemen, fifteen years added on to the life of a man between the ages of thirty and forty is a long period of time, and I trust that our comparatively new members will follow in the footsteps of the older ones, and do all in their power to carry on our Association successfully.

It is not only in a scientific sense that we have accomplished something. The meeting of members interested in the same subject from all parts of the country has been productive of friendship, and pleasant personal relations between men who otherwise would know each other only by name. I think we can congratulate ourselves, on the whole, on our harmonious meetings, and absence of the rivalry and competition which even professional men are not exempt from. As a matter of course we differ in our ideas on many points; and it is this very fact that gives a great value to our meetings, where we can discuss our differences, and have our angles smoothed down by contact with

others. If everybody thought alike, this world would be a very stupid one to live in, and all progress and advancement in knowledge and science would cease.

### THE PRESIDENT'S ADDRESS

DELIVERED BEFORE THE AMERICAN PEDIATRIC SOCIETY, WASHINGTON, SEPT. 22, 1891.

BY T. M. ROTCH, M.D., OF BOSTON.

GENTLEMEN, FELLOW-MEMBERS OF THE AMERICAN PEDIATRIC SOCIETY:—Three years have passed by since in this very city we crystallized into being and became an entity. Again we gather together to emphasize our individuality as a recognized Society. Now, however, as a part of a national organization, ourselves national in every sense of the word, with our members enrolled from the shores of the Pacific, from the South, from what was formerly the West, now the great centre of our Commonwealth, from the Atlantic coast, and then stretching still farther to the North, from our sister country Canada.

I bid you welcome to our National Capital! I congratulate you on the progress which every year is being made in the study of a most interesting as well as important branch of Medical Science; in the branch which is to help make the people of the future in our great Republic worthy of the responsibilities which such a Republic brings with it; which is to make our American citizens both physically and mentally, year by year, decade by decade, superior to their forefathers, and thus enable them to develop their country and its vast resources; thus make her stand shoulder to shoulder, neck to neck, in the race for supremacy which is going on all the world over. A young country in comparison with our medical competitors in the old world, well fitting is it that our Society should devote itself to a subject essentially young not only in years, but young in the knowledge which up to the present time has been acquired concerning it. So much less has been done in the proper and scientific study of children than at other periods of life, that it is no wonder we have entered upon the especial investigation of and research in this branch of anthropology, with the keen interest of explorers in an almost unknown country. Of still further interest, also, when we discover not only that there is a vast expanse of unknown, but that much which was supposed to be known is, in reality, a poor subterfuge of unreal facts forming structures of misleading results, which in the scientific medicine of adults would not for a second be tolerated; in fact, would be laughed to scorn as relics of the dark ages of necromancy. This same misnamed medical knowledge, however, when representing the infant and child, has been accepted with but little question. What our Society was needed for, what it was formed for, what it intends to do, is to place the study of Pediatrics on the same elevated plane that has been established for the diseases of adult life.

To accomplish this, it must in the early years of its existence be iconoclastic. It must break down and sweep away these misleading structures; clear the ground of these undesirable remnants of the past; get down to the virgin soil, and then by original research build up our new fabric on a stable basis.

Wise Iconoclasm and Patient Originality must be the weapons by which we shall fight our way to the

front and place the standard of Pediatrics where it ought to be. Place it side by side with the already perfected anatomical and physiological investigations, which have become the true basis for the enlightened clinical study of human beings.

To intelligently understand the fully-developed man in health and disease, it seems self-evident that the anatomy and physiology not only of the final state of growth should be studied, but also that the various stages of development, from embryo to infant, and infant to child, and child to adult, should successively be dealt with. This in the past, however, has been but little done. On the contrary, the very opposite method has been adopted; the most careful attention being paid to adult anatomy and physiology, and then deductions made backward from adult to child; a retrograde means of acquiring knowledge which has proved eminently unsuccessful.

In the old world as well as in the new we find that these false methods have been pursued. What little has by more rational methods of study been accomplished in the investigation of infants and children, has as large a place in America as in Europe. Here, then, is our opportunity for original research, for we have a branch of medicine which universally is new.

We have the same advantages in clinical material, in well equipped laboratories, in special hospitals as are to be found anywhere. Let us be sure that we give as much if not more to the savants of Europe as we receive from them.

As I look upon the members of our Pediatric Society and see how well fitted they are to be leaders in the several communities wherein their lot is cast, it is impressed upon me that, when meeting as a whole, our Society should represent advanced and general ideas; should deal with living questions of the day; and, that the results of our deliberations should authoritatively be promulgated by our individual representatives far and wide throughout our whole country.

Thus only can the unenlightened influence of the profession at large on the laity be curbed in the harm which it is continually doing to scientific medicine; thus only can the self-sufficient ignorance regarding the most critical period of human existence be properly combated, and the general physician be forced to understand that he has but a limited knowledge of what he has been in the habit of considering simple questions; of what he has been accustomed to give off-hand opinions and advice on, to the credulous mother of the suffering child.

You probably all have met with the same experience as mine, not only among the poorer class of physicians, but, astonishing as it still seems to me, among the highly educated and distinguished members of our profession.

Among men who are recognized leaders; men who have done much for humanity in other branches of medicine, and yet with dignified authority continue to utter dead platitudes concerning children—platitudes which have been handed down from their forefathers or copied from the already cumbersome literature of Pediatrics and again enunciated by themselves in their own writings.

It is no exaggeration to state that a large number of sick infants and young children throughout the land are suffering from the vigorous treatment of their zealous medical attendants, rather than from the disease with which they started. This should be stopped.

This it is the mission of our own Society to put an end to.

I ask you to carefully consider this vital question. I ask you to attack it with Iconoclasm and Original Thought, for I assure you it will repay you, by opening up vast fields of intensely interesting brain work.

It is not difficult to pick out instance after instance of the truth of what I have just said. The therapeutics of infancy and childhood, as understood by thousands of practitioners in Germany and France, in England and in America, is a wonderful exhibition of what vagaries the human mind, sound on other subjects, can be induced to indulge in. A total disregard of natural processes; an over-exaggeration of symptoms, which in the adult mean danger and require active treatment, while in the child, they are but simple and harmless manifestations of an over-excited nervous system. Such is the "Ignis Fatuus," so misleading, not only to those who have not especially studied the early stages of life, but also to those who have seen much of it, but with eyes blinded by traditions of the past. It would seem as though in this age of rapid discovery, of quick change and interchange of ideas—in an age when the precision of our investigators in all branches of research has almost placed the much abused profession of medicine on a level with the exact sciences—it would seem, I say, that we, who are endeavoring to place our especial branch of study on firmer ground, should consider with unusual care the opinions which we express to the profession at large and to the laity; that our writings should be founded on principles as accurate as the science of the day can make them. This, however, in the past has been but little done, and consequently we have amassed volumes of most unreliable pediatric literature. I honestly believe that there is reason for saying this. I truly think that it is one of the vital living questions of the day which we should appreciate and grapple with.

What we need to aid us in this reform, for a reform it must be in every sense of the word, is a fitting humility as to the degree of our knowledge; a proper sense of how small has been the true working capital which we have had at our command in the study of Pediatrics.

We must confess, and by so doing we certainly add new strength to our writings, that the medical science of the present day is too vast for one mind to master as a whole; for one man to attempt to be an expert in.

We must make use of the experts in their several branches, whether it be chemistry or physiology, anatomy or bacteriology, to strengthen and make stable our general deductions as clinical investigators. In this way only can we, in an age essentially one of progress in details, prepare ourselves to produce work of true original thought, of real intrinsic value.

Work which, with its lustre of matured and well proved thought, spreading far into the future, will be deemed worthy to be placed with the other records of a lasting literature.

The literature of a society gives evidence of the work which has been done by its members long after their individual labors have ceased and their places have been filled by a younger generation. If that literature is well considered and shows evidence of representing not the hasty judgment of the day, but of being built on the broad foundation of exact science, it will be worthy of the study of our descendants. As a sound unquestioned nucleus, it will give encourage-

ment to broaden the field of inquiry and to add fresh knowledge year by year.

Let us then see that the circumference of our literary circle, small as it now is, shall spread wider and wider, honestly fitting itself for the far-outstretching eternal criticism which will judge our work long ages after we are dead and gone.

Let us leave to the coming ages a fitting centre for that scientific, human, eternal progress spoken of in the old hymn which says,

"Eternity, Eternity!  
How long art thou, Eternity!  
A ring whose orbit still extends,  
And ne'er beginning, never ends,  
Always thy centre, ring immense,  
And never thy circumference,  
Mark well, O man, Eternity!"

It should be our aim that a lasting literature of this kind, ever young and fresh in the truths which it enunciates, ever presenting a solid centre for more extended investigations, should emanate from members of our own Society.

Again then, let us see that what we write, that what we publish, not only in our transactions, but in our books and in the medical journals of the day, shall form volumes worthy of the admiration, and not of the derision of our successors. Let our books so teem with unquestioned truths, with pages recording facts and finding no place for theories, that on their face they will prove the truth, and not the fallacy of the lines, which in the present age of unbridled literature might well be questioned: lines which read:

"Give books: they live when you are dead;  
Light on the darkened mind they shed:  
Good seed they sow from age to age,  
Through all this mortal pilgrimage,  
They nurse the germ of holy trust;  
They wake untired when you are dust."

### THE CONDITION AND PROSPECTS OF THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE, AND ITS INDEX CATALOGUE.

BY JOHN S. BILLINGS, M.D., *Surgeon United States Army.*

Of late years those physicians in this country who make use of medical literature in connection with their investigations or writings, have, for the most part, become acquainted with the resources of the "Library of the Surgeon-General's Office," as it is officially designated, and many of them are much interested in its progress and prospects. I am often asked how the collection is progressing, how near it is to completion, what it is most in need of, when the "Index Catalogue" will be done, whether it will be followed by an appendix, whether there is danger that the work of the library may be checked in the future through change in administration, and so on.

The eminent patrons of interest are, of course, very gratifying, and when the Chairman of your Programme Committee demanded a ten minute paper from me on this occasion, it occurred to me that I would try to answer some of the foregoing questions so far as I am able to do so.

The present condition of the library is fairly satis-

factory. It now contains 102,000 volumes and 152,000 pamphlets, counting as pamphlets all octavos and smaller sizes having less than 100 pages, and all quartos of less than 50 pages. During the last five years, that is, from July 1, 1886, to June 30, 1891, the additions to it have included 25,237 volumes and 55,900 pamphlets, or an average of 5,000 volumes and nearly 12,000 pamphlets yearly. Of this annual increase, about 2,000 volumes and 4,000 pamphlets have been of new or current literature, and the remainder have been publications of previous years or centuries. About one-fifth of these accessions, of both new and old literature, have been presented, the remainder have been purchased. So far as mere size goes, it is the largest collection of medical literature in the world, and for the last five years has been increasing more rapidly than any other similar library containing 25,000 volumes and upward. It is especially rich in medical periodicals and transactions of societies, of which classes it now contains about 34,350 volumes. The American, English, French and German literature in all branches of medicine which has appeared during the present century is very fully represented, and over 90 per cent. of all the medical literature of the world for the last ten years is in the library. The whole is conveniently arranged in a fireproof building, and is catalogued.

So much for the favorable side of the situation; now for a statement of some of the principal defects and deficiencies. Of medical incunabula, it contains 140 volumes, or about one-eighth of the medical works published prior to 1500. Of the published works of the ancient Greek, Roman, Arab and Hebrew medical authors, it has one or more editions of nearly all, but these editions are not in every instance the best. Of the early Spanish and Portuguese medical literature, it has almost nothing; of French medical works of the sixteenth century, but little; of French medical theses prior to 1800, very few. Of the English, French and German medical books of the sixteenth, seventeenth, and eighteenth centuries, which are of any importance historically or practically, it has about 75 per cent.; of the Italian, about 50 per cent.; and of Spanish, about 25 per cent. In its periodical literature it is especially deficient in the Spanish and Italian prior to about 1850, in the French prior to 1780, and in the Russian prior to 1860. If I could add to it about ten thousand volumes of my own selection, it would, I think, contain at least one edition of every medical work of any practical use or importance which has ever been published, although it would still not possess some 50,000 pamphlets and theses, each of which might be of some historical interest.

These deficiencies in the library are being gradually supplied, but the acquisition of the older books and pamphlets which are still wanted is becoming every year a slower, more difficult, and more costly process. This is due to the fact that the books still wanted are many of them rare, and only appear in the market at intervals of from five to fifty years; to the fact that the number of competitors for such books is increasing, and, above all, to the fact that the expenditure of time required for the examination of the numerous catalogues and lists received at the library in order to select those books which are still wanted is becoming very great in proportion to the results obtained. To check off a catalogue of a thousand medical books with the result of finding about four which are really

desirable, a dozen which may be accepted as filling gaps, and about twenty small theses which are not in the collection, involves an amount of clerical work which costs as much as, if not more than, the books thus obtained. In one sense, it is true that this is a satisfactory condition for a library to be in, but, nevertheless, the time spent in such checking is to be regretted.

With regard to current medical literature, the amount increases each year, but the rate of increase is becoming slower. Comparing the period of 1890 with that of 1880, we find that the number of medical writers increased from 11,600 to about 14,200, or a little over 22 per cent. There were published in 1890 about 2,000 volumes and 4,000 theses, pamphlets, and reports in medical literature. Of the volumes, about 930, or not quite half, were furnished by medical journals and transactions, as against 864 of the same kind in 1880—being an increase of about  $7\frac{1}{2}$  per cent. Excluding the journals, transactions, and theses, the number of medical books and pamphlets published in 1890 was about 1,850 as against 1,600 in 1880—being an increase of about  $15\frac{1}{2}$  per cent. This indicates that the increase in the number of medical writers, and in the quantity of medical literature which they have produced, has not been proportionally as great as the increase in population and in the number of physicians in civilized countries during the decade, which confirms the statement which I made ten years ago, that the rate of increase is becoming smaller.

In the United States the proportion of periodical literature to the whole is much greater than it is in other countries—for in 1890 it produced about 250 volumes of medical periodicals, 60 volumes of new medical books, 20 volumes of later editions, and 28 volumes of reprints of English books and transactions; while France produced about 160 volumes of medical periodicals, 250 volumes of new medical books, 20 volumes of later editions, and 15 volumes of transactions; Great Britain about 85 volumes of periodicals, 140 new books, 45 volumes of later editions, and 12 volumes of transactions; and Germany about 175 volumes of medical periodicals, 175 volumes of new books, 80 volumes of later editions, and a dozen volumes of transactions. All this is exclusive of pamphlets. Of course, quantity in medical literature has no definite relations with quality or value, but I am speaking now merely with reference to the number of separate pieces which are to be obtained, catalogued, and cared for, and you will see that including journals, transactions, reports, books, pamphlets, reprints, and theses, we shall have at least 6,000 new pieces to provide for this year. The indexing of articles in journals and transactions will involve the writing and classifying of about 25,000 titles in addition.

Of the "Index Catalogue" of the library, twelve volumes have now been printed—carrying the work to S. The thirteenth volume is nearly ready for the press, and the manuscript for the rest of the work—at least two volumes more—has been prepared, but has not yet been finally corrected and arranged. As we can print but one volume a year, it is evident that during the twelve years which have elapsed since the publication was commenced a large number of titles of books and articles received too late to be placed in their proper places must have accumulated, and this accumulation becomes more rapid every year as we get further down the alphabet in the course of print-

ing the work. At present the number of unprinted titles thus accumulated under authors and subjects down to S, probably amounts to about 70,000 author and 240,000 subject titles, the latter of course including the titles of indexed journal articles. If these were now printed they would make about four volumes of the size of the volumes of the "Index Catalogue," and three years hence, when this first series of the "Catalogue" is finished, there will probably be material on hand enough to form at least five volumes of a supplement or second series, which will no doubt expand into six volumes by the time the printing of this second series is finished—that is, if the library continues to increase as it has done for the last five years.

The twelve volumes of the "Index Catalogue" already printed contain 137,578 author-titles covering 66,855 volumes and 120,000 pamphlets, 522,092 subject-titles covering 129,284 titles of books and pamphlets, and 393,808 articles in journals and transactions. The titles of articles in journals and transactions are printed only under subject-headings, those of books and separately paged pamphlets and reprints are printed twice—once under the name of the author, and once under the name of the subject. All the cards for journal articles have been preserved, and when the printing of the catalogue is completed, it is proposed to assort these by authors so as to bring under each man's name the title of all the articles he has written which have been indexed. Whether this will ever be printed I do not know. The chief errors in the "Index Catalogue" are those of omission. About fifty serious errors in the first twelve volumes have thus far been detected, but the main defect is the failure to include under the proper subject-headings some books and journal articles which are in the collection. We have gained experience as the work has progressed, and the later volumes seem to be more full and accurate than the first.

Of main and subordinate subject-headings the "Index Catalogue," as a whole, contains about 20,000, and in placing the proper headings on the subject cards to indicate where each is to be placed, it is necessary, in order to secure good results, that the person doing this shall not only remember the general scheme of classification, but the details of between four and five thousand of the subject-headings used. If he makes an error, the card goes to the wrong place and is liable to be omitted in printing; but, in the long run, it is sure to be discovered and placed where it belongs.

In connection with the "Index Catalogue" a few words with regard to the "Index Medicus" may be of interest. This, as you know, is in the main a record of the titles of new books and articles in periodicals received at the library, to which are added the titles of a few books advertised as published but not yet received. It is not published by the Government, but by Mr. George S. Davis, of Detroit, who pays all expenses connected with it, and is entitled to the thanks of all who use it, for his public spirit and enterprise in maintaining its existence, since the amount received by him for subscriptions, barely meets the cost of its publication. At present 482 subscriptions are made for this periodical, of which 90 come from the United States Army Medical Department, 224 from the rest of the United States, and 168 from other countries. Of the subscriptions from foreign countries, Australia

sends 5; Belgium, 2; Brazil, 1; Canada, 2; England, 41; France, 26; Germany and Austro-Hungary, 63; India, 1; Ireland, 2; Italy, 1; Mexico, 1; Russia, 9; Scotland, 9; Sweden, 2; and Switzerland, 2. Of the home subscribers, California furnished 8; Colorado, 1; Connecticut, 3; District of Columbia, 13; Georgia, 2; Illinois, 9; Kentucky, 1; Louisiana, 3; Maine, 2; Maryland, 10; Massachusetts, 31; Michigan, 8; Missouri, 4; Nebraska, 1; New Jersey, 5; New York, 69; Ohio, 8; Pennsylvania, 33; Rhode Island, 4; South Carolina, 1; Tennessee, 1; Vermont, 1; Virginia, 1; Wisconsin, 4. For the large cities, the figures are, New York, 50; Philadelphia, 32; Boston, 24; Baltimore, 10; Cincinnati, 7; Chicago, 6; San Francisco, 4; Detroit, 4; and St. Louis, 3.

This is the last of the statistics of the library and matters connected with it, which will be inflicted on you at this time. The figures themselves may be dull, but some interesting, and even amusing, conclusions may be drawn from them, which I leave for you to do.

In conclusion, I may say that the future prospects of the library are excellent. It is not dependent on the skill, or energy, or good-will, of any one man; it is becoming more and more known to, and more and more used by, the members of the medical profession, and so long as they are interested in it, the necessary appropriations will be made and the skilled force employed to increase, preserve and catalogue it. The service rendered by a number of those employed in the library is not a mere matter of money—they are deeply interested in their work and proud of the results, and they can and will carry it on and instruct others who will come after them to do likewise. They have to handle much rubbish, for the proportion of what is both new and true is not much greater in medicine than it is in theology, but in a great national collection this is unavoidable, and the best they can do is to make a first rough assortment, and then make the whole accessible to those who wish to use it. There is no doubt that the publication of the "Index Catalogue" will be completed, nor that a supplement will speedily follow.

Just at present the most unsatisfactory thing about the library is the fact that many of its books and journals are not fully available for use, owing to the fact that we cannot get them bound. Under existing laws all the binding of the library must be done at the government printing office, which has not room nor men sufficient to do the work required for the different departments of the Government and for members of Congress. The result is that the library now has about 10,000 unbound volumes, and this number is increasing every year. When a journal is sent to be bound it may be six months or more before it is returned. With the erection of additional accommodations for the government printing office, it is to be hoped that this evil will in time be abated; but there will always be more or less delay in making recent books and periodicals available for use under the present system. The most effectual remedy would be a change in the law, whereby the library could have its own binding done in its own building, and under its own control.

BREAD FOR THE GERMAN ARMY.—Owing to the excessive price of rye, the German Government has decided to use wheat in making bread for the army.

## INTESTINAL PERFORATION IN TYPHOID FEVER; ITS PROGNOSIS AND TREATMENT.<sup>1</sup>

BY REGINALD H. FITZ, M.D.,

Shattuck Professor of Pathological Anatomy in Harvard University, and Physician to the Massachusetts General Hospital.

At the fifth Annual Meeting of the Association of American Physicians, Dr. Reeves,<sup>2</sup> in his paper on Typhoid Fever, says, "I have seen in five instances all the symptoms which announce and follow perforation of the bowels, yet the patients recovered." During the subsequent discussion, Dr. Loomis<sup>3</sup> stated, "I do not remember to have seen a single recovery after there were unmistakable evidences of intestinal perforation. Recovery from a local peritonitis complicating typhoid fever is not uncommon, but when the characteristic symptoms of intestinal perforation are present, in my experience, a fatal issue soon follows."

With such a divergence of opinion, so lately expressed, it seems desirable to reinvestigate the subject of intestinal perforation in typhoid fever, with the view of harmonizing conflicting opinions concerning its mortality, and, especially, with the hope of obtaining evidence which might aid in the treatment of this usually, if not invariably, fatal complication.

The frequency of its occurrence has been most recently considered by Schulz<sup>4</sup> who found that peritonitis from intestinal perforation took place in 1.2% of 3,686 cases of typhoid fever, treated in the Hamburg Hospitals during the years 1886 and 1887. He thus essentially confirms the statement of Liebermeister<sup>5</sup> who found intestinal perforation in 1.3% of rather more than 2,000 typhoid patients in the hospital at Bale between 1865 and 1872.

As a cause of death in fatal cases of typhoid fever it was found by Hölscher<sup>6</sup> to occur in 6% of 2,000 cases.

Murchison<sup>7</sup> found a much greater frequency, 11.38% in 1,721 cases collected from various sources. But in 4,680 cases of typhoid fever, as tabulated by various authors, I find a mortality of only 6.58% from this cause, thus practically agreeing with Hölscher.

It occurs much more often in man than in woman. In 441 cases, I find it among men in 71% and among women in 29%. Its occurrence among children is very rare. Wolberg<sup>8</sup> found no case of intestinal perforation among 277 cases of typhoid children in the Warsaw hospital. The following table, representing a collection of cases chiefly from periodical literature, shows the relative frequency of the occurrence of intestinal perforation in typhoid, at the different periods of life.

AGE AT WHICH PERFORATION OCCURS.			
Ages.	Cases.	Per cent.	
1 to 10 years . . . . .	7	3.6	
10 to 20 " . . . . .	46	23.8	
20 to 30 " . . . . .	77	39.8	
30 to 40 " . . . . .	15	23.3	
40 to 50 " . . . . .	14	7.2	
50 to 60 " . . . . .	2	1	
60 to 70 " . . . . .	1	.5	
	192		

The perforation may take place from the end of the first week to the sixteenth week, as shown by the

Eleventh . . . . .		3	
Twelfth . . . . .		1	
Sixteenth . . . . .		1	
		193	

The seat of the perforation in 167 cases was: the ileum in 136 (81.4%), the large intestine in 20 (12.9%), the vermiform appendix in five, Meckel's diverticulum in four, and the jejunum in two. In 19 cases there were two perforations, in three there were five, in one there were four, and in four there were several. In one case<sup>9</sup> there were 25 to 30 holes, and in another<sup>10</sup> there were 30.

The duration of life after the symptoms of perforation arose was usually short. Of 134 cases, 37.3% died on the first day, 29.5% on the second day, and 83.4% during the first week following the onset of the symptoms. During the second week nine died, four during the third week, while one lived 30 days and another 38 days.

There is no definite relation between the severity of the individual attack and the occurrence of perforation. In about one-fourth of nearly 200 cases, the course of the disease was distinctly stated as mild. Cases of walking typhoid in which perforation took place were numerous, 14 in all. Sévestre<sup>11</sup> reports one under his observation as "of typhoid fever without marked signs till the outbreak of grave symptoms." The case is reported by Bennett<sup>12</sup> of a man who was admitted to St. Thomas's Hospital for cardiac disease, with general dropsy. He was purged and, in consequence of his voracious appetite, was allowed liberal diet, including meat. After a fortnight his bowels became loose for a couple of days. Complaint was then made of general distress. There was some abdominal tenderness, which was thought to be due to peritoneal inflammation from affection of the kidneys. Sudden death took place the next day from typhoid perforation of the ileum. Finucane<sup>13</sup> reports a case as apparently well till within two days of his death, when symptoms of perforation took place. Kleinwächter<sup>14</sup> records a similar case. The patient, a woman, was about her business till forty-eight hours before death, when the symptoms of perforation began.

As the cases of typhoid fever in which intestinal perforation occurs, may be mild or severe, so may the symptoms of perforation be absent or latent, gradual or sudden. Of 80 cases in which a record is made of these characteristics, it was found that in 56 the onset of the symptoms was sudden, in 15 cases the symptoms were gradual or latent, while in five there were no symptoms whatever of perforation.

Laboulbène<sup>15</sup> reports two cases of peritonitis in typhoid fever from perforation discovered after death, "not having during life the ordinary and characteristic symptoms . . . there was neither severe pain, vomiting nor tympany. The only signs which attracted my attention and which made me think of the possibility of intestinal hæmorrhage, was a lowering of the axillary temperature with considerable chilliness of the skin." Barth<sup>16</sup> had a somewhat similar experience. He says, "it was impossible, despite the closest watching, to determine, with certainty, the moment of perforation; the patient had neither violent abdominal pain, vomiting nor collapse, and only the somewhat sudden lowering of the temperature on the morning of the 9th of February, led us to suppose, afterwards, that the onset of the disturbance then took place."

Jenner<sup>17</sup> reports the case of a patient who, on the ninth day, left his bed unassisted but with some difficulty, and died some hours later, there being no complaint of pain during the day.

Differences of opinion concerning the fatality of intestinal perforation in typhoid fever have existed for many years. The earlier investigators, as Louis,<sup>18</sup> Chomel,<sup>19</sup> and Jenner<sup>20</sup> reported numerous cases of fatal perforation, but none of recovery. Tweedie<sup>21</sup> stated that, "Intestinal perforation is always fatal, generally within thirty-six hours." The possibility of recovery seems to have been first suggested in the case reported by Buhl,<sup>22</sup> who states that, "One of the cases of perforative peritonitis was interesting because death was not the immediate result of the perforation, since the hole was completely closed. Death occurred on the forty-fifth day of the disease and twenty-three days after the earliest symptom of perforation. It was the result of hæmorrhage from a small artery opening into the intestine near the piece of mesentery which covered the hole." Griesinger<sup>23</sup> after referring to the above case, and giving the history of one of his patients who died nine days after symptoms of perforation had taken place, admitted the possibility of the healing of a perforation and of recovery, "never in cases of general peritonitis, only when the inflammation is wholly circumscribed." "The rare exceptions are hardly worth considering in connection with the prognosis which is to be regarded as almost fatal when the symptoms of perforation are distinct and as absolutely fatal when gas is present over the liver." A somewhat more favorable opinion was held by Murchison,<sup>24</sup> who asserted that "rare cases are met with where recovery ensues after all the symptoms of peritonitis from perforation." Since the publication of Murchison's classical work the writers of medical text-books have generally held the same opinion, and medical literature contains occasional reports of cases of recovery. It is our task, therefore, to consider the evidence which warrants the view that recovery ever takes place.

The evidence of recovery from intestinal perforation in typhoid fever consists, almost exclusively, in the reports of cases of recovery from peritonitis in typhoid fever, following so-called symptoms of perforation of the intestine. These symptoms are, in brief, a sudden

severe abdominal pain, often associated with collapse, at times with a lowered temperature, which is subsequently elevated. The abdomen is rigid and tender, and becomes swollen, tense and tympanitic. But little importance is to be attached to the disappearance of hepatic dulness and to the presence of a gurgling sound on respiration, as evidence of gas in the peritoneal cavity in consequence of a perforated intestine.

The former sign may be due to an abnormally small liver or to an overlying piece of intestine, and the dullness is usually found to persist when the intestine is actually shown to be perforated.

Traube,<sup>25</sup> in calling attention to this sign, stated the importance of the previous determination of the normal outlines of the liver dulness. Tschudnowsky's<sup>26</sup> observation of an abdominal murmur, louder and longer on inspiration, shorter and feebler on expiration, attributed to the passage of gas in and out of the hole in the bowel, has been confirmed by Lewaschow.<sup>27</sup> Botkin,<sup>28</sup> however, states that this sign may exist without perforation of the intestine. The rarity of the recognition of either of these signs in the literature of intestinal perforation, is sufficient evidence of their slight value, while the conditions of their occurrence, perforation with the considerable free discharge of intestinal gas, is comparatively infrequent.

The so-called symptoms of perforation merely indicate the beginning of a peritonitis, and may be present as the result of other local causes of peritonitis in typhoid fever than a perforative enteritis. Very rare, though possible, are the various causes of acute intestinal obstruction. Murchison<sup>29</sup> mentions softened infarctions of the spleen, softened mesenteric glands, abscesses in the wall of the urinary bladder, ovarian abscesses, "the bursting inwards of a pseudo-abscess in the sheath of the rectus-muscle," and, finally, perforating ulcers of the gall-bladder. Rupture of the spleen may be added, as in the case reported by Kiemann,<sup>30</sup> which gave rise to no symptoms suggesting rupture or peritonitis. Sorel<sup>31</sup> reports a case of sub-acute peritonitis the result of an abscess of the liver. A like cause gave rise to a rapidly fatal peritonitis in the case reported by Daly.<sup>32</sup>

Still another source of acute peritonitis in typhoid fever is to be found in the Fallopian tube, as in the case reported by Wilson.<sup>33</sup> His patient, a child of twelve years, died thirty-six hours after the sudden onset of abdominal pain, which was attributed to a salpingitis of the left Fallopian tube, found at the post-mortem examination. Beginning ulceration of Peyer's patches was present in the lower part of the ilium. Ranquo<sup>34</sup> credits Bourdon with a case which may have been of a like nature. The patient was nineteen years old. After several days of prolonged symptoms she was seized with abdominal pain, a violent chill and suppression of the catamenia. Death took place six days later. There were beginning typhoid ulcers, but no perforation. The same author refers to Jaccoud as reporting a case of peritonitis in typhoid fever from rupture of the urinary bladder.

Still another cause of peritonitis in typhoid fever is illustrated in the case reported by Hoffmann.<sup>35</sup> The patient gave birth to a child during the course of the fever, and died of diphtheritic endometritis and general peritonitis.

It is unnecessary to call attention to the numerous fatal cases of peritonitis in typhoid fever, in which no local cause for the peritonitis was found. Jenner<sup>36</sup> early published an article on the "Symptoms of Perforation of the Intestine without Existence of that Lesion." Of the case observed by him, he says: "All the symptoms said to denote the occurrence of perforation of the intestine were also present, but in her case, an examination of the body after death found those symptoms might be present without any traumatic lesion of the peritoneum." Wood,<sup>37</sup> a few years later, thus remarks: "I was compelled, therefore, to regard the case as one of peritonitis without perforation. No discoverable cause of the affection existed. . . . This case is calculated to throw great doubt upon the existence of intestinal perforation in those instances of peritonitis occurring in the advanced stage of typhoid fever, in which cures have been effected, of which I have been so fortunate as to witness two in my own experience. They may have been, as in the case just related, nothing more than simple peritonitis without any opening whatever through the coats of the bowel."

Since perforation of the intestine in typhoid fever may take place without any suggestive symptoms, and since suggestive, even so-called characteristic symptoms, may occur without any perforation having taken place, it must be admitted that recovery from such symptoms is no satisfactory evidence of recovery from perforation.

(To be continued.)

## HEREDITARY AND TRAUMATIC MOTOR TABES.<sup>1</sup>

BY PHILIP COOMBS KNAPP, A.M., M.D.,  
Clinical Instructor in Diseases of the Nervous System, Harvard Medical School.

THE myelopathic origin of that form of progressive muscular atrophy which begins in the small muscles of the hand is now almost universally conceded. Raymond,<sup>2</sup> in his recent monograph on muscular atrophies, regards the scapulo-humeral type of progressive atrophy, described by Vulpian, as a myelopathy, basing his decision on an autopsy by Pierret and Troisier. The myelopathic origin of progressive muscular atrophy beginning in the lower extremities is still in doubt, but the majority of writers are disposed to believe that the peroneal type, first described by Charcot, Marie and Tooth, is also due to an affection of the large motor cells of the anterior cornua.

In the revision of the forms of progressive muscular atrophy rendered necessary by the work of the last ten years, many ideas advanced by earlier writers have been abandoned. Progressive atrophies beginning elsewhere than in the three regions just mentioned are not recognized as of myelopathic origin, except the bulbar type of motor tabes. Heredity, once uni-

<sup>1</sup> Read before the New York Neurological Society, March 3, 1891. Follow Schultze in using the term motor tabes as including progressive spinal muscular atrophy, amyotrophic lateral sclerosis and bulbar paralysis.

<sup>2</sup> Op. cit.

<sup>3</sup> Med. Times, 1886, xxi, 405.

<sup>4</sup> Trans. Col. Phys., Philadelphia, 1863, 56, ii, 351.

versally admitted as a cause of motor tabes, is now doubted by Raymond,<sup>3</sup> after a careful analysis of the most striking instances reported.

Only by careful autopsies can we distinguish absolutely between myelopathic and myopathic atrophies; but certain symptoms are held to be of some value in distinguishing between them. A case without heredity, beginning in middle life, with atrophy of the thumb muscles, with reaction of degeneration, and fibrillary twitchings, is in all probability myelopathic; if bulbar symptoms develop, this probability becomes greater. A case with pronounced heredity, beginning in childhood with atrophy of the legs, associated with pseudo-hypertrophy, and unattended by reaction of degeneration or fibrillary twitchings, is in all probability myopathic. Inferences drawn from the symptoms without the confirmation of autopsy have only a partial value; nevertheless, in spite of the striking heredity and the starting-point of the atrophy, I am disposed to regard the following case, from the age of onset and the existence of fibrillary twitchings and electrical changes, as a form of motor tabes rather than as a form of primary myopathy. Other affections giving rise to atrophy may safely be excluded.

F. L., thirty-four, married, a real-estate agent, was referred to me in July, 1889, by Dr. F. M. Johnson of Boston. He had previously consulted Dr. G. L. Walton, who made the diagnosis of progressive muscular atrophy, and gave an unfavorable prognosis.

On inquiring into the heredity, the patient told me that his mother was a D— of Wayland, and that in her family was a curious disease known as the "D— disease," akin to paralysis. I could get little information from him about it, or about any members of his family, and later he wrote that he thought his own trouble bore no relation to this disease, and asked me not to inquire of any of his relatives as they were very sensitive about it. A year later he told Dr. Walton that various relatives had had a form of muscular atrophy.

On inquiring into this "D— disease" I discovered much that was interesting. Dr. Oviatt of South Sudbury, very kindly wrote me: "There certainly is a disease known as the dreadful D— disease. It must be one of two—progressive muscular atrophy or progressive spinal paralysis. Five members of the D— family have died from its effects in the past seventy years. The symptoms are loss of sensation and motion, first in the hands or feet, gradually extending over the entire system. Two cases before death were unable to move any member save the head. One member of the family now living in town has had some trouble with his feet within the past few years, and is quite anxious about the future. The disease has in most instances been painless. I have not learned whether or not there was a loss of weight. The last-named person is not my patient, and I cannot tell you exactly what his symptoms are."

Further inquiry showed that my patient's mother had died of the disease. A few weeks before her death a lady who saw her told me that all her limbs were helpless; she was unable to move her hand in greeting; but she could talk perfectly well, and had no mental disturbance. She looked well; whether

there was any atrophy my informant could not say. The present generation are very nervous, and, if they have any slight illness, fear that it is the beginning of this disease. My patient's mother had four sisters and two brothers. Of the sisters I could learn nothing. One brother died of small-pox; the other is alive and well, and has a daughter, also well. The father (my patient's maternal grandfather) was drowned. He had a sister, of whom I could learn nothing, and four brothers, of whom three, if not four, had the disease. One of these brothers, having the disease himself, had a daughter who also had it. It was thought that the disease had occurred in a previous generation, but concerning this I could get no definite knowledge. The disease was said to come on gradually and to lead to paralysis of all the limbs. In two cases the limbs were much wasted; in a third case the patient was "swollen as big as a beer barrel."

My patient himself had used much tobacco, but little alcohol. A year before the present trouble began he was kicked by a horse in the front of the right thigh, about the junction of the middle and upper thirds. The injury caused no fracture, left no scar, and was not regarded as very serious. Six months before the present trouble he had gonorrhoea, but he denies syphilis. Otherwise he has been well and strong.

In October, 1888, he noticed one night, on going to bed, a twitching in the muscles of the right thigh, which has never ceased, has extended to the other leg, and has involved the muscles below the knee. Occasionally he thought he felt a very slight twitching in the arms and across the loins, in the deltoid, and the outer side of the upper arm more particularly. With this twitching there has been a loss of power in the right leg, confined for some time to the thigh, and associated with wasting and flabbiness of the muscles. Considerably later the lower leg was affected, the ankle turned under him very readily, and he could not move the toes well. There had been some soreness in the inner and lower part of the thigh, but never any pain, numbness, or tingling. He had occasional cramps in the foot and thigh, worse in the sole of the foot. He slept well, had no headache, diplopia, or mental disturbance. His sight and hearing were good. He accepted the prognosis given with much fortitude, but he naturally had the hope that the former decision of Dr. Walton might be reversed, and was somewhat discouraged to find it confirmed. He could talk and swallow as well as ever. With the exception of some palpitation, due, he thought, to tobacco, he had had no disturbance with any of the thoracic, digestive, or urinary organs.

The patient was a large, well-developed, muscular man. The pupils, eyes, face, jaws, and tongue moved normally. The ophthalmoscope revealed nothing. The voice was a trifle husky, but he ascribed it to catarrh, and the pharynx was somewhat reddened. He could take and hold a high note pretty well, but the pitch fell off a trifle. Examination of the chest was negative. The arms were not wasted; all movements could be performed with good strength and accuracy; no fibrillary twitchings were noted; the muscles reacted to a mild faradic current; and the triceps and radial reflexes were normal and alike on the two sides. The sensibility all over the body in its various forms was normal. He could rise from a stooping posture without difficulty.

<sup>3</sup> Raymond: *Atrophies Musculaires et Maladies Amyotrophiques*, p. 119.

<sup>4</sup> Raymond: *Op. cit.*, p. 131.

become rather easily tired, and he occasionally has cramps in them, but no stiffness. With the exception of a slight pain in the side and some cough he felt perfectly well. Tactile sensibility in the hands was good but touching the ring and little fingers caused a tingling sensation. Deep pressure over the median nerve was somewhat painful on the right side; but pressure over other nerves caused no pain. All movements of the right hand could be made, but abduction and adduction of the fingers was imperfectly performed. The right hand, he said, used to be the stronger, but the dynamometer registered 55, to 90 for the left. There was distinct atrophy of the interossei and thenar muscles of the right hand, but the electrical reactions were unchanged. Measurements of the arms gave the following results:

	Right.	Left.
Upper arm, down . . . . .	10 ins.	10½ ins.
"    up . . . . .	11½ "	11½ "
Forearm . . . . .	9½ "	9½ "
"    contracted . . . . .	9½ "	10½ "
Hand under knuckles . . . . .	8½ "	8½ "

There was no atrophy elsewhere, and no bulbar symptoms. The skin reflexes were normal, the knee-jerks slightly increased, the triceps and radial reflexes were more marked on the right, and the ulnar reflex was present only on the right. Further examination was negative, except that the patient had Riggs's disease, but there was no lead line. The patient failed to return to the clinique and subsequent efforts to find him have proved unavailing.

As the influence of trauma in producing chronic degenerative processes in the central nervous system is still somewhat in dispute, I have thought it of some interest to add the following case, probably of traumatic origin, and pretty clearly myelopathic. It seems somewhat doubtful what muscles were first involved, but the morbid process had involved the upper arm as much as the forearm.

Crowell B., fifty-five, married, employed in a rubber factory, but having more or less to do with metal work, castings, etc., using more or less lead, was referred to me in March, 1889, by Dr. C. M. Godding, of Providence, R. I. He had always been fairly well; his habits had been temperate; and he had never had lead colic. His gums were spongy, and there was a very questionable blue line. A year ago he fell, striking his right elbow with some force; but he paid little attention to it, was not laid up, and did not lose the use of the arm. After the fall, however, the present trouble gradually developed, and the right arm grew weak. In August, 1888, he noticed rather suddenly that he could not hold a pen. Before and since that time, with the weakness, there had been a constant ache in the arm, from the shoulder down; this aching was of variable intensity, and was worse in wet weather, but it increased in severity pretty steadily. There were no peculiar sensations in the arm except the pain and a throbbing from the shoulder to the hand. Cold made the pain worse. The arm had wasted considerably. The hand had swollen at times. In the last month, since an attack of influenza, he had been more easily fatigued on walking. In October, 1888, he began to notice twitchings of the muscles of the arm, which have persisted, and have extended to the other side. Within two weeks he had noticed a similar throbbing in the left shoulder, going down to the thumb, but there had been no pain or weakness in that arm. At times, usually on Sundays, after extra work on Satur-

day, he had a headache. His sight and hearing were good, and there never was diplopia. In the morning his mouth felt dry, so that at first it was a little difficult to swallow; but, with this exception, he had no difficulty in swallowing, and no increased flow of saliva was noticed. He had no pain in the back, and no respiratory, digestive or urinary symptoms.

The patient was well developed, fairly nourished, with pronounced atrophy of the right arm. The movements of the eyes and pupils were normal, and the ophthalmoscope showed no changes. Movements of the muscles of the jaws, face and tongue were natural; there was a slight fibrillary tremor of the tongue, but no tremor of the lips. His speech was not affected. There was weakness of all the muscles of the right arm, including the muscles of the shoulder. Most of the movements of the arm could be made, but all were feeble. He could not completely raise or supinate the arm, spread the fingers or oppose the thumb. The right upper arm was an inch smaller round than the left, and the forearm three-quarters of an inch smaller, all the muscles apparently being involved. There was some wasting of the shoulder muscles, and pronounced atrophy of the thenar muscles and the interossei. There was no marked wasting of the left arm.

There were constant and very pronounced twitchings in the muscles, affecting sometimes a very few fibres, and sometimes large bundles of fibres. These twitchings were very marked in both arms, and in the pectoral and scapular muscles of both sides: they were also present in a very slight degree in the legs.

These twitchings were so constant, so frequent, and so great as to render it impossible to test the electrical reactions with any accuracy. The deltoid, biceps, and triceps apparently reacted alike to faradism on the two sides. The reactions of the muscles of the right forearm could not be determined. The flexor brevis pollicis could be tested. It required a stronger faradic current to produce a reaction on the right, and the galvanic reactions were diminished, slow and altered.

Right.	Left.
Ka SZ 8 Ma.	Ka SZ 4.5 Ma.
An SZ 6 Ma.	An SZ 7 Ma. (Erb's 10 sq. cm. electrode, Edelmann galvanometer.)

The right hand was stiff, and passive extension of the fingers, and passive movements of the hand and shoulder were impaired. The right arm was colder, there was some stasis, and he stated that it was more sensitive to cold. The sensibility in the arms to touch, pain, pressure, location, temperature, form, position and motion was good. The tendon reflexes of the arms were very greatly increased. The knee-jerk was slightly more marked on the right, and a patella twitch could be obtained on that side through the trousers. There was no clonus. The right arm was somewhat tender to pressure, but the tenderness was not especially over the nerves. There was no special spinal tenderness. Examination elsewhere was negative.

I advised him to take iodide of potassium in full doses (thirty grains), and to try galvanism, in the hope that lead might have had something to do with the trouble, but the treatment proved unavailing, and the trouble made a steady progress.

In June, 1890, Dr. Godding informed me that he had well-marked symptoms of bulbar paralysis, and since then he writes as follows:

"Mr. B. is still alive, but he is in a most pitiable

condition. He is totally paralyzed, as far as voluntary motion is concerned, below the muscles of the neck, although when he is placed upright in a chair, he can stay in that position. He cannot change his position in the least without assistance. The bulbar symptoms are progressing very slowly. He can still swallow solid food as a rule fairly well, but liquids give the greatest trouble, and often cannot be taken at all. Speech is entirely gone. He can make inarticulate sounds, which to my ear are all alike, but his wife, from familiarity with his wants, can still at times catch his meaning. There is at times great difficulty in breathing from dryness of the throat and hypertrophic rhinitis. There are at times large accumulations of tenacious mucus in the throat, which he cannot expectorate, and which have to be removed with a swab. He has developed some hysterical symptoms, laughing and crying immoderately at times. The muscular atrophy has progressed to a considerable extent. The pain, which when you saw him was mostly in the right shoulder, has been of late confined to the left arm and shoulder, and it can be controlled only by opiates."

The onset of bulbar symptoms renders the diagnosis of motor tabes most probable.

## Medical Progress.

### RECENT PROGRESS IN GYNECOLOGY.

By F. H. DAVENPORT, M.D.,  
Instructor in Gynecology, Harvard Medical School.

#### EFFECT OF VENTRO-FIXATION OF THE UTERUS ON SUBSEQUENT PREGNANCY.

DR. S. GOTTSCHALK<sup>1</sup> gives the history of a case which throws some light upon the question of the behavior of a uterus which has been the subject of ventro-fixation, in the event of a subsequent pregnancy. The patient was operated upon for an ovarian cyst, and at the same time the retro-flexed uterus was fastened to the lower angle of the abdominal wound. It remained in normal position for a year, when conception occurred. In the third month the patient aborted, and as it was necessary on the following day to remove the products of conception, the following state of things was observed: The body of the uterus, enlarged to the corresponding period of pregnancy, was anteverted and firmly adherent to the abdominal wall, the cervix high up, almost out of reach. On bimanual examination of the uterine cavity the anterior wall was found to be thicker than normal, the posterior, on the contrary, thinner. This condition Gottschalk explains on the supposition that as the anterior wall could not, on account of the adhesions, stretch as the ovum increased in size, the posterior wall became distended to its maximum, and in consequence the miscarriage resulted.

This case would justify the opinion of Kustner that pregnancy following this operation will usually end in abortion. On the contrary, Olshausen<sup>2</sup> cites a case operated on by Kaltenbach in 1887, where pregnancy went to full term, at which time there were no adhesions present. Gottschalk admits the possibility of the adhesions giving way as Olshausen says, "through the marked changes in the circulation of the genital organs during pregnancy," but also refers to the possi-

bility that they had become separated before conception occurred.

#### THIOL IN DISEASES OF WOMEN.

Gottschalk<sup>3</sup> recommends this new drug as a substitute for ichthyol, on account of its absolute freedom from odor. He employed it first for para- and peri-metric exudations, using tampons soaked in a ten to twenty per cent. solution of thiol in glycerine, which are changed every second day. At the same time a salve of thiol is rubbed into the abdomen. This in a few days causes an irritation similar to iodine. Under this treatment Gottschalk has seen large exudations disappear in a few weeks.

For erosions he uses the dry thiol powdered on the vaginal portion, and for endometritis the liquid preparation applied to the canal by means of cotton on a probe. In all these methods he finds the drug very satisfactory.

#### THE FAVORABLE TIME FOR IMPREGNATION, AND THE VITALITY OF THE SPERMATOZOEA.

Prof. Bosse<sup>4</sup> has made some interesting studies on these points, about which considerable differences of opinion have prevailed among authorities.

First, as to the most favorable time for impregnation. His first series of observations were with women who became pregnant for the first time immediately after marriage, and wives of sailors where the date of intercourse could be definitely established followed by periods of long absence.

There were twenty-seven such cases, in all of which except one the date of confinement made it probable that impregnation occurred during the four days immediately following menstruation. In the exceptional case, intercourse took place seven days before menstruation, and not again for a month. There are two alternatives, either that the confinement was tardy, as it did not occur until the 285th day, or that as the author has shown is possible, the spermatozoa retained their vitality in the vagina until after the menstruation, and impregnation occurred then.

His second series of observations is of cases of artificial impregnation. He reports eleven cases, of which nine were successful. In one the successful injection was made the day before the menstruation occurred. In the remaining eight, after several unsuccessful attempts at other periods, the successful injection was made in five cases in the twenty-four hours following the cessation of the catamenia; in two, on the second day; and in one, on the third day.

His third series of experiments was made to determine the length of time during which the spermatozoa retained their vitality in the vagina. His methods which should be studied in the original were apparently conducted with the most scrupulous care, and the results he arrived at were as follows:

(1) Of eight cases where the semen was deposited in the vagina before the menstruation and examined for afterwards, in four no spermatozoa were found; in three they were found alive; in one dead.

(2) Of twelve cases where the semen was deposited after the menstrual period, in four no spermatozoa were found; in eight they were found living at from three to seventeen days subsequently. These investigations justify the author in concluding that the favorable time for impregnation is immediately after the

<sup>1</sup> *Contributions to Gynecology*, No 8, 1891.  
<sup>2</sup> *Z. f. Geburtsh. u. Gyn.*, 1887, ix, p. 240.

<sup>3</sup> *Cent. für Gyn.*, No 12, 1891.

<sup>4</sup> *Nouvelles Arch. d'Obs. et de Gyn.*, April 25, 1891.

catamenia, that the spermatozoa may retain their vitality for at least seventeen days in the vagina and even through a menstrual period, and that cases of prolonged gestation may be explained by the fact that fecundation may have taken place a number of days after the last cohabitation.

While there is a great liability to error in investigating so delicate a subject as this, yet these observations seem to have been very carefully made, and are a valuable contribution to the subject.

#### TWO NEW METHODS FOR THE CLOSURE OF RECTO-VAGINAL FISTULÆ.

Le Dentu<sup>5</sup> proposes a new method for cases of recto-vaginal fistula. He prepares a flap in the shape of a half-moon, immediately below the vaginal opening into the vagina, then refreshes a corresponding surface above the fistula, and unites the flap to the refreshed surface. In this way there results a valve-like closure.

It is not applicable when the fistula is high up in the vagina, or when it opens into the vulva, or is very large.

Felizet<sup>6</sup> describes still another method. He splits the perineum transversely to a point above the fistula. In this way two fistulæ result, a vagino-perineal and a recto-perineal. The first is closed by sutures, and the latter is opened up through the sphincter and anterior rectal wall in the same manner as for the ordinary fistula in ano. The gases and fecal masses escape through the free opening, and allow the vaginal fistula to close.

#### GONORRHOEA OF THE TUBES AND PERITONEUM.

Martin<sup>7</sup> examined the contents of the tubes in twenty-six cases of pyo-salpinx, and in eight cases found bacteria of various kinds which in three cases were the characteristic gonococci of Neisser. Two of the patients recovered from the operation, one died thirty-six hours after laparotomy from septic purulent peritonitis, probably caused by the escape of pus into the peritoneal cavity at the time of the operation. A careful bacteriological investigation failed to find any gonococci in the contents of the peritoneum.

Martin says that the question whether the gonococcus Neisser which has an especial predilection for mucous membranes with cylinder epithelium, and under occasional conditions is found in pavement epithelium, if placed in an active state on the peritoneum can cause a true gonorrhoeal peritonitis, cannot be settled until a large number of well-proven cases are at hand.

#### MENSTRUATION AND OVULATION IN THEIR MUTUAL RELATIONS.

Steinhaus<sup>8</sup> in a prize essay published in Leipzig has very exhaustively treated this subject, and has advanced a new theory of menstruation and its relation to ovulation.

The first part is historical, and gives a critical account of what has been written from the first notice of the subject in Sanscrit 1,400 years before Christ to the present time.

The second part discusses the various theories of menstruation and ovulation under special heads: (1) ovulation; (2) menstruation; (3) ovulation and menstruation during pregnancy and lactation; (4) men-

struation after castration, and ovulation after hysterectomy; (5) ovulation and menstruation considered in their mutual relations.

The third part deals more in detail with the theory of menstruation in its relation to ovulation; and the author, by looking at the subject in a new light, seeks to reconcile some of the contradictions and to give a rational explanation. He does not find any ground in facts for supposing a dependence of menstruation as a function of a specially differentiated part of the excretory canal of a gland, upon the function of the gland itself, that is, upon ovulation. It is different when we consider, not the function of the ovary, but the organ itself. If the ovary atrophies or is removed, atrophy of the canal leading from it occurs; in consequence of this atrophy of the remaining genital organs, menstruation ceases. On this theory the difficulty between the facts, that, after castration menstruation stops, and that menstruation is independent of ovulation, is removed.

#### CONTRIBUTION TO THE STUDY OF OVULATION AND MENSTRUATION.

Cohustein<sup>9</sup> undertakes in this article to determine whether an artificial irritation of the ovaries is capable of producing the vaso-motor reflex necessary for menstruation, and also what rôle special conditions, as, for example, irritation of the external genitals, play in the causation of the menstrual flow. In his investigations he employed women whose ovaries could be easily palpated, the object of his investigations being to determine whether menstruation could be brought on by manual compression of the ovaries.

His results are as follows: (1) There exists a periodical and causal connection between the ovarian and the catamenial functions. The ovarian changes precede the uterine, and determine them. (2) If the ovarian activity is suspended, neither menstruation nor any of the accompanying changes in the uterus occur. (3) Ovarian activity may occur without menstruation, as, for instance, during lactation. The functional activity of an ovary can be inferred from its reaction to irritation. (4) Menstruation can be brought on before its regular time, but it is always preceded by changes in the ovary, induced, for example, by irritation from pressure. (5) The ovaries seem to alternate in the production of follicles ready to burst. (6) That Graafian follicles can ripen at any time is not proven, nor can menstrual bleeding or uterine changes occur at any given time in the intermenstrual period.

#### VENTRAL FIXATION.

Strelen<sup>10</sup> describes the method which P. Müller employs in his operations for the relief of prolapsus uteri by ventral fixation, and gives the details of eleven operations, six of which were complicated with abdominal tumors, and five were of simple prolapse. The results were by no means satisfactory, as in only two cases did a definite cure follow.

Delagenière<sup>11</sup> considers ventro-fixation indicated in prolapse of the uterus, in cases of extreme retro-deviation with adhesions, and in cases of backward displacement without adhesions as soon as serious symptoms arise. In cases of inversion of the uterus also, he would consider laparotomy and subsequent ventro-fixation less severe a measure than vaginal amputation.

<sup>5</sup> Ann. de Gynecol., November, 1890.

<sup>6</sup> Ann. de Gynecol., January, 1891.

<sup>7</sup> Zeit. für Geb. und Gyn., xxi, 1891.

<sup>8</sup> Schmidt's Jahrb. der Gesam. Med., 1891.

<sup>9</sup> Deutsche Med. Woch., No 31, 1890.

<sup>10</sup> Unang. Dias. Bern., 1890, ref. Schmidt's Jahrb., 1891.

<sup>11</sup> Ann. de Gyn., December, 1890.

Finally, he would recommend the operation in certain cases of prolapse of the ovaries.

He reckons the mortality of the operation at a little over one per cent.; and, as regards success, out of eleven cases of prolapse there was failure in two, and of seventy-eight cases of retro-displacements, eight were not successful.

Küster,<sup>12</sup> after giving the history of several cases of prolapse and retro-version and flexion treated in various ways, gives the principles in accordance with which he treats cases of retro-flexion with adhesions.

In case the reposition cannot be accomplished bi-manually or with the sound, or the uterus cannot be held by a suitable pessary the patient should be anesthetized, and the replacement tried bi-manually, the thumb of one hand in the vagina, one or two fingers of the same hand in the rectum, and the other hand on the abdomen. If strong adhesions are present, Schultze's method of forcibly separating them should be tried.

If the adhesions will not yield, massage may be tried for a month, or they may be separated through an abdominal incision. The best method for accomplishing this is with the Paquelin thermo-cautery, which prevents hemorrhage and the reforming of the adhesions. If the uterus is freed in this way, farther treatment should depend upon the age of the patient and the condition of the tubes and ovaries. If the patient is in the child-bearing age, ventro-fixation is to be avoided, for the reason that pregnancy would result in an abortion from the inability of the uterus to grow in the right direction on account of its adherence to the abdominal walls. In such cases a pessary should be fitted. Has she passed the menopause, or if she is near it, the uterus should be sutured to the abdominal wall.

Sperling<sup>13</sup> gives the details of ten cases of retro-flexion operated upon by Leopold in accordance with his simple method of suturing the freed body of the uterus to the lower angle of the wound with from one to three silk sutures, through the whole thickness of the abdominal wall and the muscles of the uterus, and allowing them to remain from fourteen to sixteen days.

Of nineteen cases of Leopold, sixteen did perfectly well, two were made decidedly better, and one was a failure. Three of Leopold's cases became pregnant again, and had no difficulty, showing, as have Kaltensbach and Sanger, that the possible occurrence of pregnancy is no contra-indication to the operation.

As regards the lasting effect of the operation, most of Leopold's cases have been under observation several years, and all have held. The best results have been in cases where the appendages were removed at the same time.

The elector of Saxe-Coburg-Gotha has approved a law fixing the father of a lad below the age of eighteen or a girl less than fifteen years old, who goes to a ball, 150 marks.

The daily press announces that it is a common practice in European cities, and even in New York, for ladies to inject different perfumes hypodermically, by which means a perfumed perspiration is produced, which is said to add greatly to their personal charms.

## Reports of Societies.

### CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

SECOND TRIENNIAL MEETING HELD IN WASHINGTON, SEPTEMBER 22, 23, 24 AND 25, 1891.

(Concluded from No. 13, page 330.)

GENERAL SESSION.—WEDNESDAY.—SECOND DAY.

#### THE LATE MANIFESTATIONS OF SYPHILIS,

by P. S. CONNER, M.D., Cincinnati, O. More than any other disease, not excepting tuberculosis or cancer, syphilis is the common meeting ground of us all, physicians, surgeons, obstetricians, specialists, pathologists, sanitarians. Modified by transmission through a dozen generations, it is still a dreadful and dreaded ill. Were there only the early lesions, syphilis would take place among the minor ills, and this is the history in the large proportion of cases. Probably in three or four out of five of the acquired cases, the disease is short lived and does but little damage. There is, however, no means of saying in any individual that in a few months or years the disease will be eliminated. Those syphilitic by inheritance suffer from late lesions in far greater ratios than the acquired cases.

There is no sharply defined line between the early and the late constitutional symptoms. Speaking generally, the late lesions are neo-formative, the early hardly ever so; so that the gumma is the sign and seal of the tertiaries. Farther they are not communicable. As a rule, they are quietly developed. No region or organ is exempt from invasion with resulting new growths. Of most frequent occurrence are the affections of the bones and of the nervous system. The lesion of the bone may be single or multiple. The symmetrical involvement of bones is exceptional. Liquefaction is rarely observed, and suppuration only an accident. As ordinarily seen at the present day, extensively destructive and deforming bone inflammations are almost confined to the head and the nasal regions. The reason of this is probably the exposed position of the bones, the thinness of some of them, the abundance of small vessels, and the intimate fusion of mucous membrane and periosteum. In the adult and acquired, there is seldom difficulty in recognizing the specific character of the lesion.

Though a large proportion of chronic bone and joint disease in the child, the adolescent and the young adult is tubercular, yet the cases in which it is syphilitic are by no means few. This may be recognized by the location of the disease, by recognition of traces on the cornea, the teeth and the skin, by application of the therapeutic test; and when practical, by inoculation.

The most frequent and the most dangerous lesions are those of the nervous system. Dr. Horsley, in speaking of cerebral gumma, declared that "medicinal treatment in nowise cures, and only very temporarily alleviates the trouble. . . . Excision offers the only chance for the patient." Is this the fact? Has not more than temporary alleviation followed the use of the iodides? However great the advance of brain surgery in the last few years, would not the outlook of the syphilitic be worse than it is, if only in the removal of the gumma could be found a chance of recovery? The affections of motion, sensation and intellect are frequent in the order given. The first at some time and in some degree is present in every case.

<sup>12</sup> A. J. Kuster's Manual, K.H.H. Ver., No. 9, 1890.  
<sup>13</sup> Deutsche Med. Woch., No. 5, 1891.

Hysteria may mimic syphilis. It is infrequent in men, while brain syphilis is rare in women. In brain syphilis, paralysis is more common than convulsions. Sensation frequently remains unaffected. Disturbances of intelligence are almost necessarily associated with any brain lesions.

In certain cases, although rare, marked motor, sensory and intellectual disturbances occur suddenly and together. Ordinarily after sleep the patient is found in a state of stupor, from which it is possible to rouse him partially. The muscles are relaxed. The pulse ratio is decidedly lessened, the breathing is slow, and the temperature is subnormal. Under mercurial treatment, promptly and persistently maintained for many months, relief, even permanent, may be expected and secured.

Spinal lesions are of infrequent occurrence. Exostoses of the spinal canal may occur and neoplasms develop. There may be pain and paralysis affecting different parts according to the location of the lesion. A question of much interest is the causative relation of syphilis to locomotor ataxia. That the majority of ataxias have had syphilis cannot be questioned. Tabes is certainly not of true gummatous origin, nor can the sclerosis be regarded as the result of the diffused formation so often found in the cerebro-spinal axis, as in other parts of the body. Syphilitic treatment generally fails to cure or even to retard the evolution of symptoms.

There are many things about late syphilis that deserve careful study. What is the explanation of the long years of intermission with the after-development of grave functional and organic disturbances? Where has the disease been lurking all these years?

What are the relations of syphilis to other diseases and to injuries? Preëxisting tubercular disease renders probable a more severe and often a more rapid syphilitic course. To the "strumous" individual the specific infection is more dangerous than it is to others. That specific lesions may become tubercularized has been proven, but only rarely does the tubercle bacillus find a nidus in and about a syphilitic new formation. Syphilis is not likely to be inoculated on a person suffering with cancer, and if it is there is no good reason why the two diseases should not each go on in its natural way. On the other hand, cancer may, and not so very rarely does, attack an area in which there had long been specific thickening and induration, as in the chronic leucomatosa of the tongue. Once in a while a gumma undergoes cancerous degeneration, more often when situated in the tongue than elsewhere. The local affection no longer amenable to specific treatment goes on steadily from bad to worse. In certain localities, especially in the breast, a gumma may readily be mistaken for a cancer. If syphilitic growths do not become sarcomatous, they often resemble sarcomata, and many a reported successful operation for the malignant affection, has been really one in which a gumma has been removed.

As a rule, the wounds of syphilis, when the disease is in a latent stage, heal as promptly as in other cases, although union may be delayed or even prevented until after the patient has been brought under the influence of the antisyphilitic remedies. This is less true of wounds of the soft parts than those of the hard parts, as fractures, where at times false joints will form in spite of the most judicious treatment. When the specific lesions are in the process of evolu-

tion, the chances of interference with proper repair are not few, and no operation should be done at this time which can be postponed. Indeed at any time before doing an operation the success of which depends on primary union, it is well to keep the patient for several weeks under the influence of the iodides and mercurials. Very rarely does any wound become actually syphilitic. In one who has had the disease although there have been no manifestations for years, any traumatism may be the starting-point of extensive specific lesions.

In very many cases of aneurism under forty years of age, the lesion may be consequent on syphilis.

The mortality-rate of acquired syphilis is rare. In its inherited form the disease is a very grave one. Four-fifths of the pregnancies terminate prematurely.

DR. ABNER POST, Boston: In speaking of syphilis, he spoke from the standpoint of the clinician and student, and not from that of the pathologist. He called especial attention to what is known as late hereditary syphilis. This relates to those who have inherited the disease and only after a lapse of years show symptoms corresponding to the tertiary symptoms of acquired syphilis. The later forms of acquired syphilis are not necessarily a part of the case. The so-called late lesions occur much earlier in the history of the disease than we are in the habit of thinking. After the third year the chances of a recurrence grow steadily less. As a preventive of late symptoms, early treatment by mercurials must be ranked high; but no methods will allow us to promise a cure, that is, absolute immunity from subsequent attacks.

The different symptoms were taken up in order. Induration and enlargement of the lymphatic glands is one of the common symptoms of early syphilis. In late hereditary syphilis the part played by lymphatics is great.

Cutaneous lesions are second in frequency to the lesion of the nervous system in late-acquired disease.

Diseases of bones were next referred to. A difference between tuberculosis and syphilis lies in the preference of syphilis for the long bones and their shafts, while tuberculosis attacks by preference such bones as those of the wrist and ankle. Diseases of the joints are at times undoubtedly the result of syphilis.

Reference was next made to intestinal and gastric symptoms in syphilis. It is fairly well established that very serious lesions of the gastro-intestinal tract may take place. As one of the possible causes of disease of the ileo-cæcal valve, syphilis must be given a certain amount of consideration.

In diseases of the nervous system there is a large field which lies practically unexplored in congenital syphilis. An interesting question is, How much influence should a negative history have in a doubtful case? There are many cases in which the existence of syphilis is not known by the patient.

Every prognosis must be a matter of special consideration. It is the persistence of the damage and not the specific lesions that cause the persistence of the symptoms. There is something to be deduced in the manner of treatment. Anti-syphilitic treatment has great power over the active process of late lesions, but it is powerless to restore the tissue already destroyed. The attempt to destroy a syphilitic tertiary sore is, in general, futile. The late lesions of inherited syphilis are as readily controlled as those of acquired disease. The amount of iodides that may be administered is

very large. In regard to the treatment as an aid in a retrospective disease, too much value must not be placed upon this element in doubtful cases, for mercurials and iodides do have some influence over tuberculosis.

The study of syphilitic phenomena is a necessity of medical progress. The possibility of syphilis renders uncertain the diagnosis of tuberculosis and cancer and other malignant forms of disease. We need the most careful clinical studies; we need hospitals specially devoted to syphilis; we need to make its study obligatory.

The subject was further discussed by DR. ROBERT T. EDGS of Washington, and DR. JAMES NEVINS HYDE of Chicago.

#### GENERAL SESSION. — THURSDAY. — THIRD DAY.

##### FIBROID PROCESSES (CHRONIC, INTERSTITIAL, INFLAMMATION SCLEROSSES), THEIR PATHOLOGY AND ETIOLOGY, WITH ESPECIAL REFERENCE TO THE INFLUENCE OF DIATHESIS AND HEREDITY.

The discussion was opened by DR. A. L. LOOMIS of New York.

Fibroid processes cannot be spoken of as degenerations, for they imply an active process productive in character. There is always a higher than normal grade of activity in those elements which develop connective tissue. The only way in which fibroid tissue can develop, is from growing cellular elements. He excluded from the list of true fibrosis all conditions of simple preponderance of fibroid tissue from the atrophy of other elements. Two forms of fibrosis were described at length, the hyperplastic and the inflammatory. The first is due to diminished nutritive supply, to parenchymatous atrophy, to nuclear proliferation, and to connective tissue hyperplasia. The inflammatory form is due to parenchymatous degeneration, to constitutional influences, and to local attraction by the products of tissue change, positive chemotaxis.

All those agencies which diminish the vital forces by which the cell appropriates to itself its proper elements, tends to the production of fibrosis. These agencies may be mechanical, chemical or mental. Among the causes of fibrosis may be mentioned direct stimulation of fibrous growth, all conditions including limited degrees of nutritive supply, all conditions and elements which induce perverted nutrition, either degeneration or necrosis including mechanical forces, perverted or defective nutritive supply, and all toxic and trophic influences.

The relation between diathesis and fibroid processes was next considered. A diathesis may manifest itself by any bodily function displaying an activity out of proportion to the stimulant applied. In the fibroid diathesis the growth of fibroid tissue is out of proportion to the amount of stimulation. Fibroid processes are not always injurious, as is seen in cases of cured tuberculosis. In seventy cases of cured tuberculosis under the observation of the writer, fifty-four presented well-marked evidences of fibrosis. Diathesis often determines the nature or prominent action which will follow any given irritant or stimulation, provided more than one is possible; it also modifies the ratio between the established process and its causes.

DR. WILLIAM OSLER, of Baltimore, considered the fibroid process under the heads of degenerative, inflammatory, and developmental. The degenerative were

subdivided into the atrophic, the secondary degenerations, the toxic forms (as from lead, ergot, syphilis), the sclerosis associated with similar changes in the smaller arteries and capillaries. The degenerative form includes the greatest number.

The inflammatory form was subdivided into the secondary forms in consequence of reactive inflammation following hæmorrhage, tumors, foreign bodies, abscess and trauma: the sclerosis which follow primary encephalitis or myelitis.

The following questions were suggested for consideration:

(1) What is the relation of vascular change to the degenerative sclerosis? How far histologically are they mesodermal or ectodermal, or are they mixed, containing both neuroglial and collagenous connective tissue?

(2) The lobar sclerosis of children. What is the nature of the primary affection? Is it inflammatory? An encephalitis or meningo-encephalitis? Or is the essential lesion in the vessels?

(3) Developmental. Can we recognize a purely ectodermal form?

DR. CHARES L. DANA, of New York, referred to the chronic fibroid processes of the spinal cord. He classified them into, (1) primary degenerative, (2) secondary degenerative, and (3) reparative and inflammatory. The first includes locomotor ataxia, lateral sclerosis, combined sclerosis, progressive muscular atrophy, and amyotrophic sclerosis. These sclerosis are not inflammatory, but due to the destruction primarily of cells and fibres. The causes of this degeneration were either toxic substances or disturbance of nutritive equilibrium by infectious vascular strain, or imperfect nutritive supply. They are not related to any special diathesis.

The secondary fibroid processes, so-called, have been shown by French pathologists to be probably, to a great extent, neuroglial proliferations or gliosis, not a fibrosis.

The inflammatory sclerosis, including chronic myelitis, diffused myelitis and transverse myelitis, are mixed processes composed of a simple necrotic process, inflammatory processes and secondary degenerations.

DR. WILLIAM T. COUNCILMAN, of Baltimore, referred to the fibroid process as found in the liver, giving the results of investigations made in the Johns Hopkins Hospital.

The General Session of the Congress then adjourned *sine die*.

#### AMERICAN SURGICAL ASSOCIATION.

TWELFTH ANNUAL MEETING HELD IN WASHINGTON, SEPT. 22-25, 1891.

##### TUESDAY. — FIRST DAY.

THE Association was called to order by the President, DR. CLAUDIUS H. MASTIN, of Mobile, who delivered the Presidential Address.<sup>1</sup>

The next paper was by DR. D. HAYES AGNEW, an abstract of which follows:

##### PRESENT STATUS OF BRAIN SURGERY, BASED ON THE PRACTICE OF PHILADELPHIA SURGEONS.

What is the present position of brain surgery and what practical lessons can be deduced from a review

<sup>1</sup> See page 337 of the Journal.

of the recorded results in this department of surgery? The object of the author was not to glean the entire field but to confine himself to the work done by Philadelphia surgeons in trephining for epilepsy (traumatic and Jacksonian), intracranial abscess, hæmorrhage, hydrocephalus, cephalalgia, microcephalus and neoplasms.

**Traumatic Epilepsy.**—Fifty-seven cases were recorded. Of this number forty-one recovered from the operation, four died and of twelve the result is not given. Thirty-two experienced temporary relief, nine obtained no benefit, four passed out of observation, four were operated on too recently to permit of the result being determined, and four are reported cured. In one of the cases reported cured the patient has been free from attacks for twenty-eight months, in two, for ten months, and in the fourth, a branch of the great occipital nerve was found imprisoned in the bone cicatrix. While the results in these cases have not been satisfactory, it by no means follows that surgery holds out no hope against epilepsy. It is not saying too much to assume that surgery is responsible for the great majority of traumatic epileptics, though this statement does not by any means criminate the surgeon on an early day. Whenever the profession can accept the doctrine that all depressed fractures, however slight the depression, and entirely irrespective of pressure symptoms, are proper subjects for trephining, then will traumatic epilepsy largely disappear from the list of surgical diseases. It is not improbable in view of the greatly diminished risk of trephining that the operation will be extended even to cases of simple fracture or fissure of the skull.

**Jacksonian Epilepsy.**—The table contains fourteen cases. In all, the discharging centre was removed. Nine recovered and four died. Of those recovering, three had less frequent and less violent attacks, one realized slight benefit, one disappeared shortly after operation, and in two no benefit was observed. One is reported as cured, and in that case the operation was done during the present year.

**Abscess.**—Eighteen cases of this nature have been collected. Six had had fracture of the skull, two had syphilitic necrosis. In one a foreign body had entered the brain; in nine the abscess was due to middle-ear disease, and in two there had been a severe blow without fracture of the skull. All the patients died in less than fourteen days.

Five cases of trephining for *Intracranial Traumatic Hemorrhage* are recorded. In each instance the symptoms necessitating operation developed within twelve hours after the reception of the injury. Four of the five cases recovered not only from the operation but with the restoration of the suspended functions.

Of trephining for *Acute and Chronic Hydrocephalus* five cases are reported. All the cases died, one living to the forty-fifth day. As hydrocephalus is usually due to tubercular disease or to morbid growth, it is difficult to understand on what ground such operations are undertaken.

**Cephalalgia.**—Five cases are given, in each of which the focus of pain was referred to the neighborhood of a scar on the scalp. In four of the cases complete relief was afforded.

**Trephining for Microcephalus.**—Seven cases are reported, of which four died and three recovered from the operation. One of the deaths, however, was due to scarlet fever occurring shortly after the operation.

The result in successful cases is reported as moderate improvement. From the results obtained from the education of idiots, the author thought it wiser to relegate these unfortunates to special training-schools rather than to the trephine and rongeur. The debatable cases would be those accompanied with athetosis, in which condition some improvement might be obtained.

**Brain Tumors.**—Only four operations for brain tumors have been done by Philadelphia surgeons. In one the growth was a fibroma weighing four ounces. The operation was done by Dr. Keen, December 15, 1887, since which time the patient has had only six epileptic seizures. In the second case done by the same operator the tumor was in the occipital lobe and not removable. The patient died the following day from shock and hæmorrhage. In the third case no tumor was found and in the fourth a cyst occupying the cuneus was found and emptied. The patient died in thirty-six hours and at the autopsy a large sarcoma was found occupying the tempora-sphenoidal lobe.

The deductions presented by the author are as follows:

(1) That all fractures of the skull attended with depression however slight and entirely irrespective of symptoms, should in view of the late after-effects be subjected to the trephine.

(2) That trephining for traumatic epilepsy promises only palliation at best.

(3) That trephining for Jacksonian epilepsy is to be regarded as only affording temporary benefit.

(4) That trephining for abscess in view of the fact that all such cases left alone almost invariably terminate fatally, is entirely proper and that the earlier such operation is done the better.

(5) That trephining for intracranial traumatic hæmorrhage is both an imperative and highly promising operation.

(6) That trephining for cephalalgia or traumatic epilepsy, medical measures having failed, should be undertaken with every prospect of success.

(7) That trephining for hydrocephalus is a useless operation.

(8) That trephining for microcephalus, independent of athetosis, confers no credit upon surgery.

(9) That it is more than probable that as our observations multiply, the sphere of the trephine as a preliminary for the removal of brain tumors will be lessened rather than be amplified.

DR. JOHN CHENE, of Edinburgh, did not take the same depressing view in regard to traumatic epilepsy. He referred to three cases in which decided benefit had followed operation. He agreed fully with what had been said in regard to operation in depressed fracture whether symptoms be present. As regards methods, he spoke of simple measures for locating the fissure of Rolando. The upper extremity may be located by means of a piece of string, being one-half inch behind the middle. The angle may be secured by folding a square piece of paper into four, around one of the angles. Three of these parts will give the proper angle. The purification of the scalp is a difficult matter, but may be accomplished by shaving and soaking with carbolic lotion for three days. For opening the skull he advised as safer than the trephine, the gouge and mallet. For enlarging the opening the gouge forceps fill a useful purpose. For puncturing the dura and the brain he uses a Graefe knife. Ham-

orrhage from the bone may be checked by plugging with a match; bleeding from the brain by hot water. Stress was laid upon the necessity of constant watching of brain cases and illustrative cases cited.

DR. W. W. KEEN, held that every case of depressed fracture should be operated upon, even in young children; a blow upon the head not sufficient to cause fracture may produce laceration of the dura or of the cortex. In regard to linear fracture, however, he was disposed not to accept the view that operation should be performed. In regard to tapping of the ventricles, he thought that further experience and an improved technique would lead to better results. In epilepsy, he suggested the use of the bromides after operation had been done.

DR. CHARLES B. NANCREDE, Ann Arbor, reported cases in which cure had followed operation for traumatic epilepsy, in one the cure was of ten years' duration. Often cases that are reported as failures soon after the operation, prove to be cures when followed for a longer time.

DR. ROSWELL PARK, Buffalo, differed from the author as regards the results of operations for epilepsy. He had himself had cases in which decided benefit was afforded. In order to determine the effect, time must elapse so that the epileptic habit may disappear. The operation removes the anatomical cause, but ordinary therapeutic measures are needed to counteract the secondary conditions. Reference was also made to the relief afforded in brain tumors even where the removal of the growth was not contemplated. He reported two cases of craniotomy for microcephalus in which benefit had followed.

DR. H. C. WOOD, Philadelphia, thought that we should wait before coming to any conclusions as to the result of treatment either medicinal or surgical. He referred to one case in which under medicinal treatment the attacks remained absent for seven years and then returned. He advised that in these cases before the contemplated operation was performed, a mock operation should be done and the effect noted.

DR. J. J. PUTNAM, Boston, thought that a simple, smooth, depressed fracture, would not be likely to cause any symptoms; the irritation from a sharp spicula of bone probably will cause inflammation. Probably the most important element in the causation of trouble is the results of the original injury to the cortex. The interstitial changes in the cortex take the form of sclerosis, and it seems *à priori* doubtful that removal of the bone would materially affect it. The operation may not prove indifferent for the cicatrization of the incised parts may lead to harm.

MR. THOMAS PRYANT, London, had been much struck with the emphasis with which Professor Agnew had insisted upon the treatment to be followed in depressed fractures. As a practical rule he was disposed to agree with him, but there are certain exceptions; he did not think it wise to encourage practitioners to trephine and elevate every case of depressed fracture. He could recall many cases of depressed fracture, followed for years, in which no symptoms followed. Depression of the lateral aspects of the skull are not so apt to be followed by symptoms as depression of the vault of the skull. From these remarks, he said, it would naturally follow that he disagreed with the observation that in every case of fissure of the skull, operation should be done. He wished Dr. Agnew had gone more thoroughly into the reason for this state-

ment. If there has been no brain symptoms, although the blow may have been sufficient to cause fracture, it would not be wise to insist that we should at once proceed to explore to see if there is fracture. It is better to wait and watch for symptoms, being ready to operate at the first suggestion of anything wrong.

DR. D. HAYES AGNEW: In traumatic epilepsy I did not condemn operation, but curative results should not be expected from it. Its result is only one of amelioration. He could not withdraw his statement made in the paper, for in many of the cases of traumatic epilepsy, there had been no history of unconsciousness or other symptoms. There has been a blow on the head, and, many years later, epilepsy has appeared. It is impossible to determine the condition of the internal table of the skull by inspection of the external table. He had seen a simple crack in the skull with the internal plate forced downwards some distance.

#### RESECTION OF THE WRIST,

a paper by RAFAEL LAVISTA, of Mexico City, Mexico, was presented, and read by title.

#### REPORT OF A COMMITTEE ON THE RESULTS OF TREATMENT OF SIMPLE FRACTURE OF THE SHAFT OF THE FEMUR,

read by STEPHEN SMITH, M.D., New York.

At the meeting of the American Surgical Association held May 15, 1890, the following preamble and resolution was adopted.

*Whereas*, in the treatment of fractures of the shaft of the femur, the question often arises as to what is a satisfactory result in a given case, therefore,

*Resolved*, that a committee be appointed by the President, to report at the next meeting of the Association, what is their judgment, under the methods of treatment, should be considered as satisfactory results.

The following committee were appointed: Dr. Stephen Smith, New York; Dr. D. Hayes Agnew, Philadelphia; Dr. David W. Cheever, Boston; Dr. D. W. Yandell, Louisville; Dr. Chas. T. Parkes, Chicago; Dr. P. S. Conner, Cincinnati; Dr. Charles B. Nancrede, of Ann Arbor, and Dr. Hunter McGuire, Richmond, Va.

The question referred to your committee has an important bearing upon the jurisprudence of surgical practice. One of the most frequent causes of prosecution of surgeons is the alleged maltreatment of fractures of the femur.

The following circular was sent by the committee to the members, "What should be considered as a satisfactory result (other than perfect union) in the treatment of a simple fracture of the shaft of the femur?" The committee has reviewed the several questions raised and endeavored to secure a common ground on which the Association can take its position, and on which members can individually stand before the courts.

(1) *Bony union*: The necessity of firm bony union does not admit of discussion. The amount of callus should not be taken as a criterion of the success of treatment.

(2) *Relation of long axis of the fragments*. While it is the aim of the surgeon to restore the normal relation of the long axis of the fragments, yet it is generally impossible to secure exact apposition of the fracture surfaces, nor can the normal long axial line be restored with mathematical precision.

(3) *Correspondence of the anterior surfaces of the*

fragments. On this depends the position of the foot. The result of treatment, to be satisfactory, requires that the anterior surfaces be in the same plane.

(4) Length of limb. This was formerly regarded as the test of success of treatment. The records of the past show that shortening was the universal rule. The discovery of the natural discrepancy in the length of the lower limbs has considerably modified our estimate of this test. Ninety per cent. of healthy, uninjured persons have lower limbs of unequal lengths. In 35.8 per cent. the right limb is the longer; in 54.3 per cent. the left is the longer. If the amount of shortening does not exceed the average natural difference in the length of the limbs, namely, about one-half an inch, the result will be in accordance with the laws of nature in the conformation of the lower extremities. If the shortening does not exceed the extreme limit of difference in the lengths of the natural limbs, namely, about one inch, the result should be considered as satisfactory. An unsatisfactory result, as regards shortening, exists only when the amount of shortening exceeds one inch.

(5) Lameness. This is a symptom of variable importance. Some will have a limp with one-fourth inch shortening, while others will not limp with one-half or one inch shortening. In many cases the limp disappears with time, or if it continues it is the result of careless habits of the patient.

(6) Restoration of function. Essential to the function of the femur is strength of the femur at the seat of fracture, free and unimpeded action of the muscles, and proper motion of the knee-joint. The determination of the degree of restoration of function cannot be made for at least one year after cessation of treatment.

(7) Conditional results. There is a class of cases in which our estimate of results must be based upon a careful study of the special circumstances connected with the treatment of each case. Results widely different from those already given, must be regarded as satisfactory when we consider the circumstances under which the treatment is necessarily pursued. The treatment may have been conducted under circumstances in which it was impossible to secure proper apparatus, or the injury may have involved other parts, so as to prevent the patient from taking the necessary position, or the patient may have suffered from delirium or other malady.

The following conclusions were presented. A satisfactory result has been obtained in the treatment of fracture of the shaft of the femur —

- (1) When firm bony union exists.
- (2) When the long axis of the lower fragment is either directly continuous with that of the upper fragment or the axes are on nearly parallel lines, thus preventing angular deformity.
- (3) When the anterior surface of the lower fragment maintains nearly its normal relation to the plane of the upper fragment, thus preventing undue deviation of the foot from its normal position.
- (4) When the length of the limb is either exactly equal to that of its fellow, or the degree of shortening falls within the limits found to exist in 90 per cent. of healthy limbs, namely, from one-eighth of an inch to one inch.
- (5) When lameness, if present, is not due to more than one inch of shortening.
- (6) When the conditions attending the treatment prevent other results than those obtained.

## THE BOSTON

## Medical and Surgical Journal.

THURSDAY, OCTOBER 1, 1891.

*A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.*

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DANRELL & UPHAM,  
283 WASHINGTON STREET, BOSTON, MASS.

## RESEARCHES ON THE PARASITIC NATURE AND INFECTIOUSNESS OF CANCER.

At the recent International Congress of Hygiene and Demography, Drs. Shattock and Ballance announced the results of their researches on the infectiousness of cancer. For several years they have been trying to separate by cultures a specific organism from malignant tumors, and by inoculating animals with the product of the cultures to produce cancer. Thus far they have obtained only negative results. They have also transplanted fragments of living cancerous growths into the abdomen, subcutaneous tissue, and muscles of different animals (monkeys, dogs, rats, cats, sheep), but have always failed to communicate any malignant affection.

Concerning the well-known case of Langenbeck, who is said to have produced cancer in a dog from inoculation of juice from a cancer in a man, Virchow is quoted as saying: "I have myself examined the microscopical specimens of the case of lung tumor. They have more the appearances of that form of spontaneous cancer I have myself found in dogs than that of the cancer elements as found in man."

In the case of the animals that were the subjects of Shattock's and Ballance's experiments, it was invariably found that the bits of tumor, if small, were entirely absorbed. Large fragments were found entirely surrounded by an inflammatory capsule; the elements of the tumor presenting simply the lesions of coagulation necrosis. In two cases, an entire scirrhus of the breast had been introduced into the abdominal cavity of a dog, and had disappeared without leaving a trace; the wound had healed without suppuration.

Fragments of scirrhus, of epithelioma, of sarcoma, were grafted into the muscular tissue of monkeys, dogs and other animals, with positively negative results. Two white rats were fed for seven months with fragments of fresh cancerous substance (mammary scirrhus, etc.); during all this time the animals remained healthy, and a subsequent autopsy showed the digestive tube to be free from disease.

At the same meeting, Simon Duplay and Maurice Cazin, of Paris, communicated some researches on the parasitic nature of cancer. The last few years, much importance has been assigned to the presence in epithelial cancers of particular elements considered as of parasitic nature, and as belonging to the group of coccidia. These "characteristic" organisms were described by Dr. William Russell in a lecture read before the Pathological Society of London, December 3, 1890, and published in the *Lancet*, December 13th. It was especially to the study of these elements that the French pathologists devoted themselves in the examination of sixty cases of epithelioma and carcinoma. To verify the assertions of observers who claim to have noted the presence of coccidia in epithelial cancers, it seemed to them necessary to ascertain if the parasites described in these tumors really passed through the principal stages of the evolution of coccidia, an evolution which comprises two distinct periods: (1) A period of growth or of vegetation, during which the parasites present simply an amoeboid form; (2) A period of reproduction corresponding to the encysting of the amoeboid masses, followed by the formation in the interior of each cyst, of spores which themselves give rise to false bodies destined to take ultimately the amoeboid form.

In most of the pavement epitheliomas which they examined, and principally in the lobular pavement epitheliomas with epidermic "globes," they did indeed observe a whole series of figured elements evidently corresponding to the organism mentioned, and which looked much like the encysted parasites, and, in particular, the coccidia during the amoeboid period. But in no case after multiplied examinations, could they distinguish any formation which might be regarded as corresponding to the period of reproduction, and hence they could not feel themselves warranted in placing these organisms among the coccidia. They conclude that the figured elements which in their preparations bore so complete a resemblance to coccidia, were the results of a special cellular evolution, which, in the lobular pavement epithelioma is generally in relation with the formation of epidermic globes.

They have, moreover, examined from the same point of view, fifteen cases of carcinoma, and have never met among the different forms of cellular degeneration observed, any figured elements resembling coccidia. As for the *fuchsin bodies* described by Russell as parasites characteristic of cancer, they are to be regarded as simply products of hyaline degeneration, and are to be found, according to Duplay and Cazin, not only in epithelioma, but in various pathological formations that are not malignant.

THE APOTHECARY is the name of a new quarterly journal, published by the Illinois College of Pharmacy, to be devoted to pharmacy, chemistry, botany, materia medica, metrology, and to pharmaceutical education and progress. The first number is dated August, 1891.

## MEDICAL INSPECTORS IN THE PUBLIC SCHOOLS.

THE spread of contagious diseases, notably diphtheria and scarlet fever, by the congregation of children in the public schools, has been on several occasions forcibly pointed out by Dr. J. H. McCollom, physician to the Boston City Board of Health.<sup>1</sup> In the last annual report of this board it was recommended that a corps of physicians be appointed, so that each school might daily be visited, and any child, suspected of being in the least unwell, might be examined, and in case of suspicion of contagious disease, prompt isolation enforced. Acting on this recommendation, the City Council appropriated \$5,000 for this purpose. It was thought that fifty physicians would be required to do the work satisfactorily, and that probably among the younger men in the profession it would not be difficult to find that number who would do the necessary work for perhaps \$200 a year.

As the season was then nearly over, the question was laid over by the School Committee until the re-opening of the schools, and referred to the Committee on Hygiene. This committee reported adversely at the meeting of the School Committee last week, partly on the grounds that a similar question has arisen before, when the right of the committee to appoint a medical inspector was brought up, and an opinion in the negative given by the City Solicitor. This was in 1877, and again in 1880, on a question of appointing a medical instructor in hygiene. The report of the committee further says:

"Your committee are of the unanimous opinion that under the above-noted opinions of the City Solicitor, the School Committee has no right to appoint a medical inspector for the purposes set forth in the communication from the Board of Health. They feel if they have not the power of appointment, they have not the power to approve the appointments or the plan suggested. Beyond this, the committee feel that it is a serious question in their minds of the benefit really to be derived from this corps of medical inspectors. The natural antipathy of children to be examined by doctors; the strong feeling of parents of their faith in certain physicians; and other reasons which it might be easy to mention, but seem unnecessary, are strong arguments against the proposition made. It seems best to this committee to recommend that the School Board do not approve of the suggestions made by the Board of Health."

The question has been held over two weeks, and will next week come up again in the School Committee.

It surely seems desirable that any practical system which would prevent the schools from being disseminators of disease, should meet with acceptance and support. Possibly some less elaborate system than that suggested would be sufficient. In New York a somewhat similar work is undertaken by an Inspector of Schools and Institutions for Children. This inspector has in charge all sanitary matters relating to schools and institutions for children. He makes daily inspection of these, reporting the unsanitary conditions that are found. The contagious diseases occurring in them receive particular attention. Investigation of the causes of such outbreaks is carefully made, and the isolation of the sick children is supervised by him.

<sup>1</sup> See Journal of August 13, 1891, p. 161.

## MEDICAL NOTES.

**INFLUENZA.**—A severe epidemic of influenza is reported in the Spanish provinces of Caceres, Jaen and Cordova.

**THE GERMAN CONGRESS OF NATURALISTS AND PHYSICIANS** opened at Halle, September 21st. Prof. William His, Professor of Anatomy and Physiology at Leipzig, presided. There were 1,215 delegates present.

**HELMHOLTZ MEDAL.**—The contributions to the Helmholtz Testimonial Fund now amounts to 45,000 marks. The interest of this sum will be applied to the foundation of a Helmholtz Medal, to be awarded every two or three years to the young physicist who shall have published the most important work during the interval. Professor Helmholtz himself is to be the first recipient of the medal.

**THE STUDY OF CANCER.**—Professor Adamkiewicz, of Cracow, who has been making researches on the etiology and treatment of cancer, which he thinks likely to lead to important practical results, recently applied to the Austrian Minister of Education for permission to pursue his investigations in a larger clinical field than he can command at Cracow. The Minister has placed the material in the First Surgical Clinic of the Vienna General Hospital at his disposal for the purpose during the next winter semester.

**THE ILLINOIS ARMY AND NAVY MEDICAL ASSOCIATION** was organized at Springfield, on June 26, 1890, with Dr. Hosmer A. Johnson, of Chicago, as president, and Dr. John H. Rauch, of Springfield, as secretary. The objects of the Society are the consideration of social, historical and medical subjects connected with the late war. All reputable physicians now living in Illinois, whether in practice or not, who served in the army or navy during the late war, and all who were surgeons or acting assistant surgeons, who were with Illinois troops and are now non-residents of the State, are eligible to membership. At the second meeting of the Association, held in Springfield, on May 18 and 19, 1891, Dr. John H. Rauch was elected president, *vice* Dr. Johnson, deceased, and Dr. Edward P. Bartlett, of Springfield, was elected secretary.

**THE ASSOCIATION OF MILITARY SURGEONS OF THE NATIONAL GUARD OF THE UNITED STATES** was organized in Chicago, on September 18th, with a membership of about sixty. The object of the Association is to bring together surgeons of the militia of the different States, to meet at fixed intervals, for the consideration of methods of surgery and for mutual improvement. The Secretary of War detailed five surgeons of the regular army to coöperate in the organization. The Association is to meet annually. Thirty-five constitute a quorum. The officers consist of a president, first and second vice-presidents, secretary, corresponding secretary, treasurer and an executive committee of five. The initiation fee was fixed at \$5, and yearly dues at \$3. The election of officers

resulted as follows: President, Surgeon-General Senn; vice-presidents, Major Henry, New York, Colonel Chancellor, of St. Louis; secretary, Colonel Matthews, of Illinois; corresponding secretary, Colonel Chandler, of Wisconsin; treasurer, Colonel Crane, of Denver. The next meeting is to be held in St. Louis.

## BOSTON.

DR. SAMUEL A. GREEN has been appointed a member of two advisory councils of the World Congress auxiliary to the World's Columbian Exposition, the Council on Literary Congresses and the Council on a Congress of Librarians.

**MEAT INSPECTION.**—By an act passed during the last session of Congress, all meat exported from this country must undergo a government inspection at one of the five stations provided for by the Meat Inspection Bill. Four of these are situated in the West—South Omaha, Kansas City, Milwaukee and Chicago. It has been decided to establish the fifth station somewhere in the vicinity of Boston.

## NEW YORK.

**THE CROTON WATER-SUPPLY.**—Commissioner Gilroy, of the Department of Public Works, in a report just made on the Croton water-supply states that an act passed by the Legislature in June, 1890, practically and effectually renders any proceedings under the regulations of the State Board of Health nugatory. "It virtually provides," he says, "that until the city establishes at its own cost a complete sewerage system in the Croton water-shed, and removes or disposes of all sewage and other deleterious matter, and removes all objectionable buildings, nuisances, etc., after compensating the owners for interference with property rights and privileges of every description, no action for violation of the rules and regulations can hold." It being evident, in his opinion, that the powers now vested in the city authorities and the means at the disposal of his department are inadequate to preserve the purity of the water-supply, and, moreover, that no measures can be successfully carried out which do not provide a just and liberal regard for the rights and interests of the inhabitants of the Croton water-shed, he proposes, as the first step to be taken to accomplish the desired object, the acquisition in fee simple of a strip of land not less than 250 feet wide above high-water mark on each side of the principal streams, and around each lake, pond and reservoir tributary to the water-supply, at the points where nuisances now exist. The estimated cost of such a purchase is placed at \$1,092,000. He considers as beyond serious discussion the project mooted from time to time of purchasing the entire 360 square miles of water-shed, and driving 25,000 or more inhabitants from their homes.

**THE ESTIMATE OF THE COMMISSIONERS OF CHARITIES AND CORRECTION** for the year 1892 was filed at the Comptroller's office on September 23d. The appropriation asked for is \$2,877,245, as against \$2,166,237 for the present year; the increased amount being desired for the construction of new buildings

and other improvements, among which are additions to the insane asylums on Blackwell's, Ward's and Hart's Islands, and improvements at the city farm for the insane at Central Islip, Long Island.

**TYPHOID FEVER.**—During the week ending September 19th, there were reported 79 cases of typhoid fever, and 19 deaths from the disease. The average number of cases for the corresponding week for the past five years has been about 45.

### Miscellany.

#### A LEGAL DECISION CONCERNING SHIP'S SURGEONS.

In the case of *Mary O'Brien vs. The Cunard Steamship Company* the Supreme Court of Massachusetts has recently given a decision, which we give in full, as it contains, besides a question of an alleged assault, an opinion on the question of the responsibility of a corporation for the negligence of its medical officers. The plaintiff was one of the steerage passengers on the *Catalonia* in July, 1889. The decision is as follows:

This case presents two questions: First, whether there was any evidence to warrant the jury in finding that the defendant, by any of its servants or agents, committed an assault on the plaintiff; second, whether there was evidence on which the jury could have found that the defendant was guilty of negligence towards the plaintiff. To sustain the first count, which was an alleged assault, the plaintiff relied on the fact that the surgeon who was employed by the defendant vaccinated her on shipboard while she was on her passage from Queenstown to Boston. On this branch of the case the question is whether there was any evidence that the surgeon used force upon the plaintiff against her will. In determining whether the act was lawful or unlawful, the surgeon's conduct must be considered in connection with the surrounding circumstances. If the plaintiff's behavior was such as to indicate consent on her part, he was justified in his act, whatever her unexpressed feelings may have been. In determining whether she consented, he could be guided only by her overt acts and the manifestations of her feelings.

It is undisputed that at Boston there are strict quarantine regulations in regard to the examination of emigrants, to see that they are protected from small-pox by vaccination, and only those persons who hold a certificate from the medical officer of the steamship, stating that they are so protected, are permitted to land without detention in quarantine, or vaccination by the port physician. It appears that the defendant is accustomed to have its surgeons vaccinate all emigrants who desire it and who are not protected by previous vaccination, and give them a certificate, which is accepted at quarantine as evidence of their protection. Notices of the regulations at quarantine, and of the willingness of the ship's medical officer to vaccinate such as needed vaccination were posted about the ship in various languages, and on the day when the operation was performed, the surgeon had a right to presume that she and the other women who were vaccinated understood the importance and purpose of vaccination for those who bore no marks to show that they were protected. By the plaintiff's testimony, which in this particular is undisputed, it appears that about two hundred women passengers were assembled below, and she understood from conversation with them that they were to be vaccinated; that she stood about fifteen feet from the surgeon and saw them form in a line and pass in turn before him; that he examined their arms and passing some of them by, proceeded to vaccinate those that had no mark; that she did not hear him say anything to any of them; that upon being passed by, she each received a card and went on deck; that when her turn came, he showed him her arm; he looked at it, and said there was no mark, and then she should be vaccinated; that she told him she had been vaccinated before and it left no mark; that he then said nothing; that he should vaccinate her; that he then held up her arm to be vaccinated; that no one touched her; that she did not tell him she did not want to be vaccinated; and that he took the ticket which he gave her and then he had vaccinated her, and used it at quaran-

She was one of a large number of women who were vaccinated on that occasion without, so far as appeared, a word of objection from any of them. They all indicated by their conduct that

they desired to avail themselves of the provisions made for their benefit. There was nothing in the conduct of the plaintiff to indicate to the surgeon that she did not wish to obtain a card which would save her from detention at quarantine, and to be vaccinated, if necessary, for that purpose. Viewing his conduct in the light of the surrounding circumstances it was lawful; and there was no evidence tending to show that it was not. The ruling of the court on this part of the case was correct.

The plaintiff contends that, if it was lawful for the surgeon to vaccinate her, the vaccination was negligently performed. There was no evidence of want of care or precaution by the defendant in the selection of the surgeon, or in the procuring of the virus or vaccine matter. Unless there was evidence that the surgeon was negligent in performing the operation, and unless the defendant is liable for his negligence, the plaintiff must fail on the second count.

Whether there was any evidence of negligence of the surgeon we need not inquire, for we are of opinion that the defendant is not liable for his want of care in performing surgical operations. The only ground on which it is argued that the defendant is liable for his negligence is that he is a servant engaged in the defendant's business and subject to its control. We think this argument is founded on a mistaken construction of the duty imposed on the defendant by law.

By the fifth section of the Act of Congress of August 2, 1882 (22 U. S. Statutes at Large, 188), it is provided that, "Every steamship or other vessel carrying or bringing emigrant passengers, or passengers other than cabin passengers, exceeding fifty in number, shall carry a duly qualified and competent surgeon or medical practitioner, who shall be rated as such in the ship's articles, and who shall be provided with surgical instruments, medical comforts, and medicines proper and necessary for diseases and accidents incident to sea voyages, and for the proper medical treatment of such passengers during the voyage, and with such articles of food and nourishment as may be proper and necessary for preserving the health of infants and young children, and the services of such surgeon or medical practitioner shall be promptly given in any case of sickness or disease to any of the passengers, or to any infant or young child of any such passengers, who may need his services. For a violation of either of the provisions of this section, the master of the vessel shall be liable to a penalty not exceeding two hundred and fifty dollars."

Under this statute it is the duty of ship-owners to provide a competent surgeon whom the passengers may employ, if they choose, in the business of healing their wounds and curing their diseases. The law does not put the business of treating sick passengers into the charge of common carriers and make them responsible for the proper management of the vessel, or the medical assistance or surgeon does in such cases is under the control of the passengers themselves. It is their business, not the business of the carrier. They may employ the ship's surgeon, or some other physician or surgeon who happens to be on board, or they may treat themselves if they are sick, or may go without treatment if they prefer, and if they employ the surgeon they may determine how far they will submit themselves to his directions, and what of his medicines they will take and what reject, and whether they will submit to a surgical operation or take the risk of going without it. The master or owners of the ship cannot interfere in the treatment of the medical officer when he attends a passenger. He is not their servant engaged in their business and subject to their control as to his mode of treatment. They do their whole duty if they employ a duly qualified and competent surgeon and medical practitioner, and supply him with all necessary and proper instruments, medicines and medical comforts, and have him in readiness for such emergencies as may happen to employ him. This is the whole requirement of the statute of the United States applicable to such cases; and if, by the nature of their undertaking to transport passengers by sea, they are under a liability at the common law to make provision for their passengers in this respect, that liability is no greater. It is quite reasonable that the owners of a steamship used in the transportation of passengers should be required by law to provide a competent person to whom sick passengers can apply for medical treatment, and when they have supplied such a person it would be unreasonable to hold them responsible for all the particulars of his treatment when he is engaged in the business of other persons in regard to which they are powerless to interfere.

The reasons on which it is held in the courts of the United States and of Massachusetts that the owners are liable for the negligence of a pilot in navigating the ship, even though he is appointed by public agencies, and the master has no right to supersede such a person do not apply to this case. The pilot is engaged in the navigation of the ship, for which, on grounds of public policy, the owners should be held responsible. The business is theirs, and they have certain rights of control in regard to it. They may determine when and how it shall be undertaken, and the master may displace the pilot for certain causes. But in England it has been held that even in such cases the owners are not liable.

The view which we have taken of this branch of the case is fully sustained by a unanimous judgment of the Court of Appeals of New York in *Lambheim vs. De Koninglyke Stoomboot*

Maatschappij 107 N. Y., 228. See also, *Secord vs. St. Paul Railway*, 18 Fed. Rep., 221; *McDonald vs. Massachusetts General Hospital*, 120 Mass., 432. We are of opinion that on both parts of the case the rulings at the trial were correct.

### SIBERIAN PENAL FLOGGING.

DR. BENJAMIN HOWARD<sup>1</sup> describes a case of legal flogging with the knout at a Russian penal colony on an island off the eastern coast of Siberia, and describes in detail the physical condition of the culprit. This man, who before had been several times a murderer, had recently killed for the sake of a few roubles another convict who, settled on a farm of his own, had become this culprit's benefactor. In the absence of capital punishment, and the impossibility of more distant exile, the only check upon many of the more hardened murderers is the fear of the lash, of which one hundred strokes at a time is the legal maximum.

The convict, aged thirty-two, was examined by the post surgeon in the usual punctilious manner in the presence of the court, the medical examination being imperative, in all cases of flogging, within the same day as that on which the punishment is to be administered. He was thin and anæmic, but there was no evidence of any organic disease or of his being other than in his usual health. Thereupon the sentence was ordered to be duly carried out, and one hundred lashes to be given that day. The culprit, heavily loaded with leg and wrist manacles, guarded by four soldiers was marched back to his cell, and the officials, none of whom seemed to relish the coming duty, took two dinners—one immediately, another two hours afterwards. Directly after the last dinner, the governor and officials in uniform being present, a long pine table about fourteen inches high, was placed in the centre of one of the prison courtyards, upon which, after another slight examination by the surgeon, the culprit placed himself face downwards. There were slits in the top of the table through which straps passed, buckling the culprit to it immovably, his entire back, buttocks, and thighs being bare. The knout, in general shape, was much like the whip used for dog-sledge driving: a short, thick handle of wood, with a thong about twelve feet long. The thong in this case was of stout raw-hide, which for the last four feet was in three tails, the terminal end of each being formed into a stout knot. The official flogger, at the word of command, with great skill brought the three tails with a sharp recoil just upon the buttocks, shouting "One."

This was responded to by a sub-officer on the opposite side of the culprit, who also shouted "One," entering the number at the same moment in a book. This form was continued with great care to the end. Until the fifth or sixth stroke the appearance of the parts struck was as if fifteen strips of white paper had been pasted across them, so completely was the blood expelled at the points of contact at each blow. From that time forward blood spattered until the whole surface of the buttocks was covered with it. At the fiftieth stroke the executioner changed sides, so that the two buttocks which alone were struck were made to share the violence equally. Before the fifty-first stroke was commenced the post surgeon felt the patient's pulse, when, had he thought it necessary, he could have had the remaining fifty strokes postponed. During the first twenty or thirty strokes, and until

the skin was pretty generally detached, the screams of the patient were all he could make them. They gradually diminished, but were reawakened on the flogger changing sides, until the sixtieth or seventieth stroke, when they subsided entirely into groans. On being unstrapped, the patient was in a cold, clammy sweat, deadly pale, and quivering, but by the help of two soldiers was able to take steps towards the hospital. In the hospital everything had been made ready for the patient's reception, where the wound and himself received as much care as if he had met with an accident for which he was not responsible.

On admission to hospital the pulse was 120 and very weak. The treatment was cold-water dressing and the internal use of stimulants. The appetite, which was naturally very small, was humored as far as the hospital resources would allow, until it grew to be all that could be desired. For about a week the temperature varied slightly, and the pulse was weak. By the third day all the loose shreds of remaining integument and cellular tissue had become gangrenous, for which antiseptic applications were kept applied. By the twelfth day the continuous use of antiseptic poultices had yielded a fairly clean wound. Its area was about fifteen by ten inches; and its depth, which invaded the muscular tissue, varied from half an inch to an inch. It looked much like a wound from an exploded shell. After this date, as the strength of the patient increased, cicatrization proceeded from the margins as fast as could have been hoped for.

The author says in conclusion, that in Russia indifference to death is no distinction; but the terror of the knout is universal, and in places 10,000 miles from the centre of administration this form of punishment is the most prompt, economical, and effective available. From a medical standpoint the physical results of flogging, as he saw it in its various forms in Siberia, disappointed him. In every case the primary shock and also the secondary shock have been less than was expected, and, bearing in mind the alleged former fatality of flogging in the English army, unless those reports were often exaggerations, some of the difference in the after-consequences may be attributed to the difference of position of the culprit during the flogging. In England the culprit was tied up to a post—in Russia, the culprit's head is always lower than the heart and than the part flogged.

### METEOROLOGICAL RECORD.

For the week ending September 20, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Date.	Baro- meter.	Thermom- eter.	Relative humidity.	Direction of wind.	Velocity of wind.	Wet't'r. *.	Rainfall in inches.

Hyde Park	10,193	—	—	—	—	—	—	—	
Pembury	10,158	4	2	50.00	—	50.00	—	—	

Deaths reported 3,053; under five years of age 1,389; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 730, consumption 339, acute lung diseases 125, diarrhoeal diseases 361, diphtheria and croup 119, typhoid fever 133, scarlet fever 41, whooping-cough 27, cerebro-spinal meningitis 20, malarial fever 16, measles 9, erysipelas 5, puerperal diseases 5.

From scarlet fever New York 11, Chicago 8, Philadelphia 7, Brooklyn 9, Baltimore and Pittsburg 3 each, Cincinnati 2, Malden 1. From cerebro-spinal meningitis New York 4, Chicago 5, Washington 3, Brooklyn 2, Philadelphia, Lowell, New Bedford, Gloucester, Malden and Newburyport 1 each. From whooping-cough New York 5, Milwaukee and Washington 4 each, Chicago, Philadelphia and Baltimore 3 each, Brooklyn and Pittsburg 2 each, Springfield 1. From malarial fever New York 8, Brooklyn 4, Baltimore and Nashville 2 each. From measles New York 4, Brooklyn 3, Pittsburg and Milwaukee 1 each. From erysipelas New York 3, Brooklyn and Milwaukee 1 each. From puerperal diseases New York 5.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,405,408, for the week ending September 12th, the death-rate was 17.3. Deaths reported 5,115; acute diseases of the respiratory organs (London) 145, diarrhoea 273, whooping-cough 73, fever 32, measles 27, scarlet fever 27, diphtheria 24.

The death-rates ranged from 10.9 in Huddersfield to 26.2 in Sunderland, Birmingham 15.5, Bradford 19.2, Hull 16.9, Leeds 14.1, Leicester 17.2, Liverpool 22.0, London 15.0, Manchester 21.9, Newcastle-on-Tyne 24.7, Sheffield 19.6. In Edinburgh, Glasgow, and Dublin 22.1.

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 19, 1891 TO SEPTEMBER 25, 1891.

Assistant Surgeon THOMAS F. DEWITT, U. S. A., granted leave of absence for six months, on surgeon's certificate of disability.

Assistant Surgeon JEFFERSON R. KEAN, U. S. A., granted leave of absence for three months, on surgeon's certificate of disability.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING SEPTEMBER 26, 1891.

E. H. MARSTELLER, passed assistant surgeon, detached from U. S. S. "Petrel," and granted one month's leave.

O. D. NORTON, passed assistant surgeon, detached from special duty, Naval Academy, and to the U. S. S. "Petrel."

J. H. HALL, surgeon, detached from Naval Hospital, Chelsea, Mass., and placed on waiting orders.

G. P. BRADLEY, surgeon, ordered to Naval Hospital, Chelsea, Mass.

C. U. GRAY, surgeon, ordered to Naval Hospital, Brooklyn, N. Y.

J. F. GARDNER, passed assistant surgeon, detached from Naval Hospital, New York, and to the Naval Station, New London, Conn.

J. H. NORTH, assistant surgeon, detached from Navy Yard, New York, and wait orders.

GEORGE A. LUNG, assistant surgeon, detached from Naval Station, New London, Conn., and to the Navy Yard, New York.

M. H. SIMONS, surgeon, detached from the "Enterprise," and to hold himself in readiness for sea service.

## OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MAINE-HOSPITAL SERVICE, FOR THE SIX WEEKS ENDING SEPTEMBER 19, 1891.

PURVILLE, GEORGE, surgeon. Granted leave of absence for thirty days. August 22, 1891.

LONG, W. H., surgeon. Granted leave of absence for twenty-two days. August 18, 1891.

AUSTIN, H. W., surgeon. To proceed to Delaware Breakwater Quarantine Station as inspector. August 28, 1891. Granted leave of absence for thirty days. September 3, 1891.

GASSAWAY, J. M., surgeon. Granted leave of absence for ten days. September 19, 1891.

STONER, G. W., surgeon. Granted leave of absence for ten days. August 15, 1891.

CARTER, H. R., passed assistant surgeon. To proceed to Cape Charles Quarantine for temporary duty. August 27, 1891.

WHEELER, W. A., passed assistant surgeon. To proceed to Cape Charles Quarantine for temporary duty. August 27, 1891.

BANKS, C. E., passed assistant surgeon. Granted leave of absence for eleven days. September 3 and 9, 1891.

CARMICHAEL, D. A., passed assistant surgeon. Leave of absence extended thirty days, on account of sickness. September 10, 1891.

GLENNAN, A. H., passed assistant surgeon. Granted leave of absence for seven days. August 29, 1891.

GUTERAS, G. M., assistant surgeon. Relieved from duty at San Francisco, Cal., to proceed to New Orleans, La., for special duty. September 14, 1891.

WEITENBAKER, C. B., assistant surgeon. Granted leave of absence for thirty days. September 10, 1891.

PRICK, J. C., assistant surgeon. To proceed to Evansville, Ind., for temporary duty. September 18, 1891.

YOUNG, G. B., assistant surgeon. Granted leave of absence for eight days. August 29, 1891. To proceed to Cairo, Ill., for temporary duty. September 15, 1891.

HOUGHTON, E. R., assistant surgeon. To proceed to Vineyard Haven, Mass., for temporary duty. August 29, 1891. Granted leave of absence for sixty days and permission to go abroad. September 18, 1891.

## PROMOTION.

GOODWIN, H. T., assistant surgeon. Commissioned as passed assistant surgeon, to date from September 24, 1891. September 18, 1891.

## SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL OBSERVATION. — A regular meeting will be held at the Medical Library, 9 Boylston Place, on Monday, October 5, 1891, at 8 P. M.

Readers: Geo. T. Tuttle, M.D., "Kidney Disease and Insanity"; C. E. Vaughan, M.D., "A Case of General Peritonitis Caused by Chronic Abscess Originating in or near the Gall-Bladder." JOHN C. MUNRO, M.D., Secretary.

INTESTINAL PERFORATION IN TYPHOID FEVER; ITS PROGNOSIS AND TREATMENT.<sup>1</sup>

BY REGINALD H. FITZ, M.D.,

Shattuck Professor of Pathological Anatomy in Harvard University, and Physician to the Massachusetts General Hospital.

(Concluded from No. 14, page 348.)

THERE remains for consideration another set of cases, several in number, of recovery from peritonitis of sudden onset in typhoid fever following the discharge of pus, offensive or not, by the rectum, vagina or abdominal wall. Food may be present in such pus. Such statements of fact do not necessarily show a primary perforation of the intestine, for the latter may have been caused by the peritonitis, which, in its turn, may have owed its origin to some cause apart from an intestinal lesion.

One of the most marked cases of this sort is that reported by Low.<sup>23</sup> The patient, five years old, during the course of his fever developed a hard, painful swelling at the right of the navel, which burst. Offensive pus was discharged, in which were several orange-colored masses as large as beans. The abscess healed ten days later. To accept this case as evidence of recovery from a typhoid perforation of the bowel, it is necessary to assume, first, that the case was one of typhoid fever, and then that there was a communication with the bowel. Of equal, if not of greater, importance in determining the possibility of recovery after typhoid perforation of the intestine, are the cases of prolonged life after the occurrence of symptoms suggesting a perforation, with the discovery of the latter after death. Buhl's<sup>24</sup> case has already been referred to. Hoffman<sup>25</sup> records the case of a man in whom a bilateral pleurisy arose during the course of typhoid fever, at a time when the abdomen was tense, hard, and occasionally painful. Death took place after an illness of some seven months. Towards the end of this time an abscess pointed in the ileo-caecal region, and was opened. Fæcal pus eventually escaped. At the post-mortem examination it was found that the ileum was perforated and adherent to the abdominal wall. It opened into an extra-peritoneal fistula, which was continued downwards into the groin, where it opened externally, and upwards through the diaphragm beneath the pleura. Intestinal contents were thus present in the thorax, but not in the pleural cavity.

The similarity of the symptoms of typhoid perforation of the bowel and those of inflammation of the vermiform appendix is striking. Cases of perforating appendicitis have repeatedly been regarded as of typhoid fever, and, as a rule, the symptoms in typhoid fever which suggest a perforation of the bowel are those which, in the absence of typhoid fever, would be regarded as diagnostic of an appendicitis. These symptoms are not merely similar, they are actually identical, even to the usual localization of the consequent peritonitis in the right iliac fossa. However familiar this resemblance may now appear, the only conspicuous mention it has received in medical literature is by Gourounee.<sup>21</sup> To be sure, he uses the terms

typhilitis and perityphilitis without appreciating the prominent part played by the appendix in etiology, and the cases he reports make no mention of the condition of this structure. He<sup>22</sup> "speaks only of ordinary typhilitis occurring in the course of typhoid fever." The tumor is regarded as faeces accumulated in the caecum in consequence of inflammation of the caecum. He<sup>23</sup> states that "in many cases the progress of the inflammation of the pericecal tissue is simultaneous with that of the caecum, but a pericecal abscess may sometimes be seen in the absence of an appreciable ulcer of the caecum."

Despite this extraordinary resemblance between the symptoms of so-called typhoid perforation of the intestine and those of perforating appendicitis, in a research made several years ago, I was enabled to find but three cases of this lesion attributable to typhoid fever. It is well known that the mucous membrane of the appendix contains numerous lymph-follicles, and that in typhoid fever these may become enlarged, necrotic and ulcerated. It is, therefore, noteworthy that but few cases of perforation of the vermiform appendix are recorded in the literature of typhoid fever. Morin<sup>24</sup> finds 12 cases in 64 (18.75%), which he collected from various sources, while Murchison<sup>25</sup> finds it but once in 39 cases. He suggests a doubt as to the nature of the disease in Morin's cases, in consequence of the large number of perforated appendices. Heschl,<sup>26</sup> among 56 cases, finds the appendix perforated in 8 (14.3%). But of 167 cases of perforated bowel in typhoid fever, collected for the purposes of this paper, I find but five cases, a fraction less than 3%, in which the appendix was reported as the seat of the perforation. Such differences may be explained, as suggested by Murchison, on the ground of an incorrect diagnosis during life. But they are quite as likely to be due to overlooking the appendix at the time of the autopsy. Even in the cases of fatal peritonitis in typhoid fever, in which it is stated that no perforation was found, there is no mention of the condition of the appendix.

Recent anatomical evidence is thus lacking of a relatively frequent perforation of the appendix in typhoid fever. Clinical evidence, on the contrary, though perhaps misunderstood, is abundant as to the probable frequency of perforative appendicitis in typhoid fever. The probability of its occurrence furnishes the best solution as to the prognosis of intestinal perforation in the latter disease. Most cases of recovery from symptoms of perforation of the bowel in typhoid fever, are those in which an attack of appendicitis is closest simulated, while the fatal cases of perforation of the bowel in typhoid fever are, in the great majority of instances, those in which other parts of the bowel than the appendix are the seat of the perforation. Hence the prognosis of apparent perforation of the bowel in typhoid fever is to be regarded as the more favorable the more closely the symptoms and course resemble those of an appendicitis.

Such a consideration at once indicates the appropriate treatment for perforation of the intestine in typhoid fever. All indubitable cases of this nature were those in which a post-mortem examination was

necessary to make the diagnosis certain. The suggestion of a laparotomy for the relief of a perforated bowel was first made by Leyden<sup>47</sup> in 1884. In the same year Mickulicz<sup>48</sup> reports a successful case of laparotomy and intestinal suture in a patient with ichorous, purulent peritonitis, attributed to a typhoid, perforating ulcer of the small intestine. The patient had a small right inguinal hernia, but thought himself well. He was suddenly seized with a violent pain in the abdomen on leaping out of bed. Symptoms of peritonitis ensued, and at the end of the third day laparotomy was performed for the relief of a supposed intestinal obstruction. A median incision was made, offensive pus, in which were pieces of potato, was evacuated, and a hole was found in that part of the ileum lying above the ilium. The hole was opposite the mesenteric attachment, and was six millimetres long and four millimetres wide. Its edges were sharp, the mucous membrane not everted, and there was nothing abnormal in its vicinity except an increased redness of the intestine. The mesenteric glands were soft and about the size of hazel nuts. Mickulicz excluded the idea of a gangrenous, incarcerated hernia, because the outline of the hole was regular and oval; there were no phenomena of a reactive inflammation in its vicinity, and there was no positive evidence in favor of such a view. He claimed that the seat, size, and absence of other characteristic symptoms, excluded nearly all other than typhoid ulcers; while its position, edges, and the enlarged lymph-glands, were evidence in favor of a typhoid ulcer. Although admitting the force of his argument, there remains a question as to the existence of typhoid fever in this case. Its chief value lies rather in its being a successful case of laparotomy, where a perforation of the ileum away from the mesenteric attachment existed, than as illustrating the value of laparotomy in the treatment of intestinal perforation in typhoid fever.

The first operation for the relief of the symptoms caused by a perforating, typhoid ulcer of the intestine where there is no question as to the nature and seat of the lesion, was performed in 1887, by Lücke.<sup>49</sup> The symptoms suggestive of perforation took place on the eighteenth day of the disease and a laparotomy was performed twelve hours after their onset. The edges of the ulcer were cut out and the hole closed by sutures. The operation lasted some two hours and the patient died a few hours later. The hole in the ileum was about a foot and a half above the valve.

In the same year Bontecou<sup>50</sup> operated upon a case of typhoid perforation thirty-six hours after the onset of its symptoms. The patient died. Morton<sup>51</sup> states that Mr. Bartlett, of Birmingham, had performed a laparotomy in the case of a perforating, typhoid ulcer. Death took place two days after the operation. Although feces were found in the peritoneal cavity the hole in the intestine was not discovered, nor is the evidence furnished that the case was one of typhoid fever.

At the meeting of the German Surgical Congress in 1888, Frank<sup>52</sup> stated that Hahn had operated on two cases of peritonitis from perforation in typhoid fever, but both patients died. Furbringer<sup>53</sup> also refers to

the fact of Hahn's operations on some of his patients, all of whom quickly died after the operation. He alludes to the successful operation by Wagner. The fullest mention of this case I have been able to find is as follows:<sup>54</sup> "Wagner (Königshutte), in recent years has operated in three cases; first, on a woman convalescing from typhoid fever, for perforation of an intestinal ulcer; eventration of the intestines, irrigation, sutures of the wound without drainage. Recovery."

In 1889, Senn<sup>55</sup> operated upon a patient who was thought to have a volvulus. He had been treated for chronic bronchitis for three weeks during which time he made three visits to Dr. Senn's office. The temperature was never above 101° F. At the end of the third week there was an acute attack of pain in the left iliac region, followed by vomiting which became stercoraceous. Laparotomy was performed at the end of three days. "A number of loops of the upper portion of the ileum were found enlarged twice the size of the remaining portion of distended intestine, rotated on the mesenteric axis one complete turn from left to right." While the over-distended intestine below this point was being withdrawn about a pint of fluid feces gushed from the left iliac fossa. Perforation was discovered about six inches above the ileo-cæcal valve. The hole was closed by sutures. The operation lasted an hour and death took place in the course of a few hours. Three elliptical ulcers of the ileum were found below the point of perforation.

Bontecou<sup>56</sup> operated upon a patient who was in the sixth week of typhoid fever. Seventeen hours after the onset of symptoms of perforation, a circular hole about one-fifth of an inch in diameter was found in a patch some four or five inches from the ileo-cæcal valve. The hole was closed by sutures, but the patient died after a few hours.

In the *British Medical Journal*<sup>57</sup> is the following extract from a Japanese medical journal: "Kimura, a surgeon in the Japanese navy, records a case in which he performed laparotomy for perforating typhoid ulcer. The patient was a man aged thirty-four. The operation was done twenty-eight hours after the occurrence of perforation when the patient was collapsed and almost moribund. The perforation in the small intestine, about two inches above the cæcum, was of the size of a small pea. The perforated part of the intestine was turned inwards, and ten interrupted Lembert sutures applied. The abdominal cavity was washed out with a warm solution of dilute boracic acid, dried with a sponge; a large, gum-elastic tube was introduced and the wound stitched up and dressed antiseptically. The patient was 'cheerful' for a little time, but died about nine hours and a half after the operation."

Early laparotomy in typhoid perforation of the intestine (with a reasonable doubt as to the existence of typhoid fever in three of the cases) is thus recorded to have been performed ten times. The result was fatal in every case but one, that of Wagner, a complete record of which does not appear to have been published.

The inference is direct that this operation offers but slight hope in the early stages of typhoid perforation of the intestine. A like result occurs when the perforated spot is quickly found as when a couple of hours are demanded for the operation. The lack of

<sup>57</sup> British Medical Journal, 1890, ii, 777.

success is best attributed to the condition of the patient at the time, enfeebled as he usually is between the second and fourth weeks of the disease, when the perforation is most likely to take place.

Fatal as the results of this early operation have been in cases of peritonitis from typhoid perforation of the intestine, they have been more successful when a peritoneal abscess has been incised some time after symptoms of suspected perforation have taken place.

Barthélemy<sup>58</sup> records the case of a young soldier, who, at the end of typhoid fever, had a severe, deep-seated pain in the right buttock, extending to the kidney. An abscess was recognized in the iliac and lumbar regions. An opening was made a little above the iliac crest and three litres of pus escaped. The patient recovered.

Escher<sup>59</sup> reports as a case of recovery from supposed intestinal perforation in walking typhoid, one where an abdominal incision was made for the relief of a suspected incarcerated, right inguinal hernia after the third day of abdominal symptoms.

Taylor<sup>60</sup> states that a relapse took place in a patient thought to be convalescing from a severe attack of typhoid fever. The symptoms were more acute and dangerous than at first, and, at one time, there was so much collapse that a perforation was suspected. A tumor then formed between the sternum and navel and was incised four months after the disease began. Three pints of brown, slightly turbid fluid were evacuated. The patient recovered.

Although the reported instances of the successful result of an operation for the cure of circumscribed peritonitis in typhoid fever are comparatively few, I have been able to collect a considerable number in which recovery resulted from resolution or from the spontaneous evacuation of the inflammatory product. In seventeen cases of recovery by resolution, the peritonitic attack began in the second week in one, in the third week in eight, in the fourth week in one, in the fifth week in one, and in the sixth week in two. It began at the end of the fever in one, and during convalescence in three. Recovery took place in a week in one, in two weeks in three, in three weeks in two, in four weeks in one, and in two or three months in three. The length of time necessary for recovery in the remaining cases was not stated.

I find also seventeen cases of the spontaneous discharge of the pus in peritonitis in typhoid fever. Nine patients recovered, seven died, while in one case the result was not stated. The peritonitic symptoms began in the second week in two cases, in the third week in three, in the fourth week in two; in one walking case, in six convalescent cases, and in three during the course of the disease. Death is said to have taken place in six, fourteen and fifteen days, in three weeks, and in two and one-half months after the symptoms began. The pus was discharged into the intestines in thirteen cases; into the vagina in one, through the abdominal wall in two, and at the navel in one.

It appears from this statement that of twenty-seven cases of peritonitis in typhoid fever, whatever may have been the cause of the former, though often attributed to intestinal perforation, three recovered after operation, seventeen after resolution, and nine after the

spontaneous discharge of the pus. The comparison of this series of cases with those showing the results of early laparotomy for symptoms suggesting typhoid perforation, would indicate that the appropriate treatment for this complication would be delay until a probably encapsulated exudation proved unduly slow in absorption. An incision or early laparotomy for the relief of the peritonitis seems advisable only when the patient's condition is exceptionally good. Should the signs of the exudation persist a week or more, and the general condition of the patient permit an incision, surgical treatment would then be strongly advisable. That the patient may live for weeks after perforation has taken place is illustrated by the cases of Buhl and Hoffmann already mentioned.

In brief, immediate laparotomy for the relief of suspected intestinal perforation in typhoid fever is only to be advised in the milder cases of this disease. In all others, evidence of a circumscribed peritonitis should be awaited, and may be expected in the course of a few days. Surgical relief to this condition should then be urged as soon as the strength of the patient will warrant.

#### ASEPTIC AND ANTISEPTIC DETAILS IN OPERATIVE SURGERY.<sup>1</sup>

BY J. COLLINS WARREN, M.D., OF BOSTON.

In glancing over the abstract of Dr. Gerster's paper, it occurred to me that a presentation of the routine work of some of the hospitals in Boston would be the most useful contribution that I could make to this discussion. I have selected for this purpose the two larger hospitals—the Massachusetts General and the Boston City Hospitals, and a special hospital—the Children's Hospital—which, owing partly to its limited material and partly to the very excellent work done by its hospital staff, is able to produce most satisfactory results. The larger hospitals, which are general hospitals, have such an abundant material,—the City Hospital being supplied from the city of Boston and the Massachusetts Hospital receiving patients from all parts of New England and beyond,—that the surgeons have a much more difficult problem to deal with in endeavoring to maintain a high standard of work. At the Massachusetts General Hospital, particularly on public operating days, the number of operations under ether, performed by Dr. Porter and myself during the winter months, has occasionally been as high as eighteen, and has covered a period of from five to six hours. This requires a large force of assistants and complicated preparations to preserve an aseptic standard.

The new abdominal ward is the feature of the Massachusetts General Hospital where the aseptic system is seen to best advantage, as in the amphitheatre both septic as well as aseptic cases are necessarily operated upon. This ward is entirely separated from the hospital. The patient who is to be operated upon is prepared for the operation in the general ward. The day before the operation the abdomen is shaved, scrubbed with soap and water, then with ether, and finally with corrosive sublimate (1-1000) and a corrosive poultice (1-5000) is applied for the night, and renewed in the morning. A vaginal douche, of corrosive (1-10000) or carbolic acid (1-400) is given also. Some surgeons

<sup>1</sup> Discussion of the paper by A. G. Gerster, M.D., read before the American Surgical Association, Washington, September 23, 1891.

<sup>58</sup> Ann. d. chir. franc. et étrang., 1841, Gourroumer. Op. cit.

<sup>59</sup> Wiener Med. Woch., 1887, xxxviii, 607.

<sup>60</sup> Lancet, 1890, i, 961.

scrub the abdomen with chlorinated soda, ether, and peroxide of hydrogen successively, or with permanganate of potash and oxalic acid before using the corrosive wash. The scrubbing process occupies one hour, and is much complained of by the patients. The patient, at the time appointed for the operation, is carried across an open area to the abdominal ward, where there are separate rooms for each patient and an operating theatre. The latter deserves a word here. The room is lighted at the north end and above by plate-glass. The floor is of asphalt, the walls are of marble and polished brick, and the seats are of slate. A gallery on the sides and over the entrance is allotted to students and visitors. There is no plumbing in this building connected with the sewer. The patient, as soon as convalescent, is transferred to another ward.

Instruments are sterilized for fifteen minutes in the Arnold sterilizer, or boiled according to the desire of the surgeon; after use they are scrubbed with soap and brush to remove whatever may remain upon them. If the instruments are removed from the towel immediately on being taken out of the sterilizer, there is no rusting. At the Children's Hospital they are wrapped in a towel soaked in a solution of glycerine and water (two ounces to the pint) before being placed in the sterilizer, and this is found to prevent all rusting. The ligatures used are of silk or catgut; the silk is sterilized immediately before the operation. Large-eyed or self-threading needles are used, which have been passed through a flame. The catgut is soaked in ether for several days, and is then placed in a solution of corrosive sublimate (1-100) in strong alcohol (95 per cent.). In some cases it is afterwards boiled in alcohol in a closed jar for half an hour, and then preserved in absolute alcohol. Both silk and catgut at all the hospitals are kept upon glass reels or on the small glass spools used at the Johns Hopkins. Silk or silver-wire sutures, double needled, are used for the abdominal wound. They are wrapped in a towel and sterilized. Interrupted sutures are used about two to the inch, and include the peritoneum. Between most of these there are superficial stitches.

The sponges used are made of worsted and gauze, as suggested by Dr. J. W. Elliot, and are of all sizes and shapes. Large flat sea sponges are also used to keep back the intestines. They are sterilized by steam before the operation, and are kept in weak corrosive or boiled water, according to the wish of the operator.

White duck coats are worn by the operator and his assistants. They are usually sterilized, and preserved in bags until the operation. The towels which surround the abdomen and all other towels used are either sterilized or wrung out of corrosive (1-2000).

The dressings are prepared in the ward. Corrosive or plain gauze is cut in strips, and after being folded in a towel is sterilized for half an hour. The wound having been dusted with boracic powder or aristol, the dressing is carried, still in the towel, and adjusted without being touched by the hands. Absorbent cotton is placed outside, and held in place by adhesive plaster and swaths.

In suppurating cases in this hospital small cheap sponges with a large mesh are used. These are kept, one for each day in the week, in stone jars, which hold a carbolic solution (1-20). Each day the sponges are taken out and dried, and before operation are soaked

in hot corrosive (1-3000). When it is desired to perform a dry operation, as is frequently the case in amputation of the breast, for instance, absorbent gauze, from which the oil has been removed, is cut and folded in pieces of the desired size, and sterilized in a towel, which is opened at the time of operation.

There is a general tendency at all the hospitals to use as little drainage as possible. The wounds are made as dry as possible before suturing, and buried and quilted stitches are taken when needed to prevent the accumulation of fluids in pockets. In large wounds quill drainage-tubes introduced by Dr. H. H. A. Beach are used by many surgeons. Their thin walls give a large lumen, and their blunt points protect the wound.

They are washed, and kept in corrosive (1-1000). These are removed in thirty-six to sixty hours, and the sinus closes quickly where they have been inserted. Bone drainage-tubes are used when the dressing is left undisturbed for one to two weeks. Rubber drains are used in suppurating wounds. They are kept in solution of corrosive (1-1000) or carbolic acid (1-20).

The surgeon's hands are washed first in two sets of soap and water, sometimes dipped in ether, and are afterwards scrubbed in strong corrosive. They are then soaked in a hot solution of weak corrosive, and the nails are thoroughly cleansed with the orange dental-stick (as suggested by Dr. M. H. Richardson).

Brushes used in the abdominal ward are dried after each operation, and are put in corrosive sublimate (1-1000) one-half hour before being used. In the out-patient department a brush attached to a chain is kept constantly in a solution of strong corrosive.

The vagina is prepared for an operation by a douche of four quarts of hot water the day before the operation; and after careful washing on the day of the operation, a douche of corrosive sublimate (1-10000) is used. Sulpho-naphthol or carbolic acid, in a strength of 1-400, is also used. For disinfection of wounds the following solutions are used: Corrosive sublimate, from 1-1000 to 1-10000; carbolic acid, from 1-20 to 1-40; biniodide of mercury; sulpho-naphthol.

At the City Hospital the general arrangements do not differ essentially from those above described. The preparation of the patient's skin is delayed, however, until the day of the operation. In both hospitals the soap poultice is occasionally used the night before the operation. If green soap is used, it must be worked into a lather with charpie, and then applied; otherwise it will blister the skin. A special set of very fine sponges are used for laparotomy. These are washed in very hot corrosive, then in hot water, and are kept in a glass jar in a carbolic solution (1-30).

White linen coats or frocks are worn both at the City and Children's Hospitals, and over these rubber aprons, which are scrubbed in corrosive sublimate.

The sutures are kept in rubber-tubes, which are passed through a diaphragm of rubber placed about midway in a glass jar. Beneath the diaphragm is a corrosive solution, above it is alcohol, in which the needles lie. The needles can be drawn from the jar as the surgeon needs them.

The corrosive and iodoform gauze is prepared in the hospital, cut in small squares when sent to the ward, and kept in tin boxes, from which it is removed with instruments. Dry sterilized gauze is prepared as follows: The gauze is cut in squares, soaked in ten per cent. glycerine and water solution, and heated in the dry oven to 150° C. The presence of the glycerine

prevents the charring of the gauze. Gauze is also sterilized by steam heat, and dipped in strong corrosive before use.

The catgut is prepared in a special way by the apothecary, Mr. Tucker, who has tested his material thus prepared by culture, and found it to be absolutely sterile. The catgut is allowed to stand for twenty-four hours in aniline oil, and is then heated while still in this oil to 115° C. for fifteen minutes. It is then transferred to a ten per cent. solution of glycerine in alcohol until it is soft enough to use, and is transferred to a three to four per cent. solution of glycerine in alcohol so as to render it less slippery.

The results obtained at the Children's Hospital are said to be excellent. The class of operations performed here are for the different forms of surgical tuberculosis and deformities, and also the radical cure of hernia. The organization of the operation and the care of the room is under the personal supervision of a very able sister, who has the necessary scientific knowledge. The instrument tables have slate tops. The operating table has a porcelain dish with slightly raised edges, which drains through a central hole into a pail hung beneath the table. Everything that is used during the operation is sterilized in the Arnold sterilizer. The instruments, being protected by the glycerine from rusting, are left in the towel until it is opened by the surgeon. Sterilized water is used for sponges and hands during the operation.

The patient's skin is usually prepared during etherization. In case of hernia, this is done the night before, soap and ether being used. A corrosive poultice is then left on over night. Before the operation the child's legs are covered with sterilized towels, a rubber dam being placed over them, and held in place with elastic bands. The dam is also placed about the body if necessary. Over the rubber, sterilized towels are laid. Irrigation is used during the operation. The brushes are constantly kept in a solution of corrosive (1-5000). Soap, corrosive and alcohol are used for the hands. The dressings consist of pads of absorbent cotton wrapped in sterilized gauze. These are kept in tin boxes, and are removed with instruments when applied. If pus has been found during the operation, the pads are soaked in corrosive sublimate (1-5000) before being applied. The dressings are not changed for a week or ten days. First intention is expected in abscesses as well as in wounds.

The silk used is boiled fifteen minutes, and kept twenty-four hours in a fifty per cent. solution of corrosive, and is preserved in strong alcohol. The catgut is first scrubbed with yellow soap, allowed to stand in ether forty-eight hours, in corrosive (fifty per cent.) for forty-eight hours, and finally preserved in the following solution:

Corrosive sublimate . . . .	gr. xv.
Glycerine . . . . .	3 lbs.
Absolute alcohol . . . . .	3 AXXI.

This prevents the precipitation of the corrosive. Injection of iodoformized oil into joints and abscesses have not been used for some time at this hospital. They were first employed some ten years ago, but have been largely abandoned.

As will be seen, catgut is still used in all three hospitals, and is also largely employed in private practice, and the method used for preparing it is practically the same, with one or two exceptions.

The following experiment by Brunner, of Zurich,

seems to bear ample testimony to the efficiency of the method of preparation. Brunner manufactured gut from the intestine of an animal dead of anthrax. The raw gut thus prepared, when inoculated into animals caused fatal anthrax in all cases. He succeeded in making it aseptic in the following way: The raw catgut was scrubbed in strong soft-soap (Kalisife), then placed either directly in corrosive sublimate (1-1000) or after leaving it one half-hour in ether. It was preserved finally in the following solution:

Corrosive sublimate . . . .	1 part.
Absolute alcohol . . . . .	900 parts.
Glycerine . . . . .	100 parts.

As an example of what is done in private operations, I will mention some of the details of the organization of an operation performed in a private house this summer, at which our colleague, Dr. W. W. Keen, was present.

The case was trephining for epilepsy, over the centre for the right shoulder, in a boy eight years of age. The parlor, on the second floor, was selected for the operation. The carpet was taken up; the curtains were removed; the floor was thoroughly scrubbed; and the walls and ceiling were dusted. Three dozen towels, six sheets and five white duck operating coats were sterilized, wrapped in oiled paper, and brought to the house the morning of the operation. My instruments, including the cyrtometer, were sterilized the night before, and placed in a linen bag (devised by Dr. S. J. Mixer), or wrapped in clean sheet-lint taken fresh from the roll. The worsted sponges were also sterilized and wrapped in lint.

The child's head was shaved the afternoon before, washed in soap and water, poulticed a few hours in green soap, and kept over night in a corrosive poultice (about 1-1000). It was scrubbed the last moment before the operation again in corrosive. Cheap nail-brushes made of wood-fibre bristles were used for this purpose. They sell at retail at ten cents apiece, and can be discarded after each operation. The hands were prepared as already stated. The button of bone, removed by the one and one-quarter inch trephine, was kept in a solution of corrosive sublimate (1-10000) in a glass standing in a basin of water of temperature of over 100° F. There were about one dozen fragments removed by the rongeur forceps. Warm boiled-water was allowed to trickle over the exposed brain. The bone was replaced at the conclusion of the operation. No drain was used, but a shred of corrosive gauze was placed between two stitches on the second day, to allow the serum to ooze out. This was removed two days later. The wound healed by first intention.

The dressing used consisted of Linton moist gauze, applied loosely, and held on by pads of absorbent cotton wrapped in the same gauze, and retained by a roller bandage. The catgut which I use for ligatures is prepared by soaking in ether two days. It is then placed in absolute alcohol, and is changed twice. I prefer this to the catgut of commerce as the method of preparation is not disclosed.

It is not always necessary to use sterilized linen in private practice. The best results can be obtained by a free use of towels soaked in hot solutions of corrosive sublimate. On one occasion I happened to have the opportunity to count the wash, and found that I had used five dozen pieces. The case was an extensive dissection in cancer of the breast. The temperature rose to 99° F. on the second night, and after that was normal. Union by first intention.

In regard to the technique of operating, I would urge the importance of avoiding inoculating the freshly dissected surfaces with the products of disease which are removed during the operation. This we are all fully aware of when the case is one of suppuration, but few surgeons realize the necessity of avoiding infection with the products of tuberculosis. The recent experiments in Europe in the inoculation of cancer show clearly that fragments of the growth can be grafted upon the healthy human tissues, and I have little doubt in my mind that many a case of recurrence has been due to want of care in this respect on the part of the operator.

A good deal of bruising is done by the hæmorrhagic forceps, particularly if the skin is included. Small sloughs form, which, although they do not endanger the wound, delay union somewhat. More care should be employed in their application.

Sealing by collodion is common in Boston as early as the second or third day, even in operations of some magnitude. But this dressing is not used in the hospitals as a primary dressing in laparotomy, or in large wounds like excisions of the breast.

A well circumscribed collection of pus forms an abscess which heals easily after a moderate sized opening, if well washed out at the time of operation. Burrowing pus must, however, be followed relentlessly and without delay. It must be remembered that the exclusion of air favors the growth of anaerobic organisms, and that it is only by free cutting that this tendency can be overcome. Multiple incisions should be substituted, if possible, for the enormously long incisions which are coming into fashion. The question of stitch abscess seems to me an important one to settle. This does not appear to depend so much upon the aseptic quality of the thread used as is supposed. Deep stitches are liable to wound large vessels. A stitch hæmatoma increases tension and is liable to infection through the suture sinus from the septic layer of the epidermis above. Tight dressings are often a cause of septic infection. Experimental work in this direction would have a practical value.

## Clinical Department.

### GYNECOLOGICAL CASES AT THE ST. ELIZABETH'S HOSPITAL.

REPORTED BY DR. F. W. JOHNSON, M.D.

REPORTED BY DR. F. B. ROSS, House-Officer.

THE following cases are selected from among those operated on during Dr. Johnson's term of service, December, 1890, to March, 1891. Somewhat over a year ago an in-door department for gynecology was established at St. Elizabeth's Hospital, and put under the charge of four gynecological surgeons. Since then a similar department has been established at the Carney Hospital.

Through the kindness of the corporation and the staff a ward containing twelve beds was put at the disposal of this department, and in conjunction with the other members of the staff it was allowed the use of eight private rooms. The nursing in the gynecological department is first class, being under the direct supervision of one of the Sisters of St. Francis who has had extended experience in the care of this class of patients.

We have every facility in the way of operating-room, instruments, sterilizers, and assistance, for abdominal work.

Cœliotomy was done seven times; Alexander-Adams operation was done eleven times; carcinoma uteri was operated on twice; electrolysis for uterine fibroid was done twice; one case each of operation for malignant adenoma and laceration of the cervix; one case of imperforate hymen; one operation for complete rupture of the perineum.

All instruments, ligatures, sponges and towels are rendered aseptic by being kept for one-half hour in confined steam. The sterilizer is so made that only as many compartments as are necessary for a particular operation need be used. The greatest care is exercised in securing clean hands and clean finger-nails. After every cœliotomy an abdominal supporter of elastic silk is made for each patient. The supporter is worn every day for one year to diminish the liability to hernia.

CASE I. Cœliotomy: Removal of abscess of left ovary.

A. T., single, twenty-nine years of age, entered the out-patient department with a history of pain in right ovarian region for seven years, and occasional pain in left ovarian region. Unable to work. Menstruation began at fourteen. Flows one day every four weeks. Flows but little. Confined to bed during menstrual periods. Frequent headaches. A diagnosis was made of retroversion with adhesion, and right salpingitis. She was treated at intervals in the out-patient department until August 8th, when she entered the hospital.

August 16th. Evidence of quite extensive inflammation about the uterus was present. From this time until December 1st she was under constant treatment in the hospital; rest in bed, iodine, hot douches and packing having been faithfully tried.

December 1st. Examination found a retroflexed adherent uterus with a mass as large as a hen's egg to the right of the uterus and apparently adherent to it.

December 6th. Examined under ether by Drs. Johnson and Conant. A tumor as large as a small orange was found to the right of the uterus and seemed to be in the right broad ligament. The left ovary as large as an English walnut was prolapsed down beside the uterus.

December 13th. Cœliotomy was performed by Dr. Johnson, assisted by Drs. Conant and Burrage. Dr. Burrage, under whose care she had been in the out-patient department, felt quite sure an enlarged tube would be found on the right side. The right tube was found distended almost to bursting, and in separating the adhesions it ruptured, allowing something less than one-half pint of thin, clear fluid to escape into the abdominal cavity. On the left side the ovary had been converted into an abscess and was everywhere adherent. While freeing it from adhesions it ruptured, and about two ounces of very foul-smelling pus escaped into the peritoneal cavity. The abscess walls were ligated off, and the mass removed.

Dr. W. F. Whitney reported: "The specimen which I received from you on Saturday I am inclined to think is ovarian rather than tubal; but shall have to wait a day or so longer before sending the final report, until I can make some good sections from the hardened specimen. The examination of the hardened specimen received from you Saturday shows it to be a multilocular cystic tumor, the size of a large plum. The external surface in places is slightly corrugated, recalling

the appearance of the surface of an ovary. The inner lining of the cysts is quite smooth. Microscopic examination of the hardened specimen shows a fibrous wall rich in cells, with large and tortuous vessels, and with here and there fibrous centres similar in character to those following menstruation. The specimen, I think, is an ovary."

After thoroughly irrigating the abdominal cavity with hot boiled-water, and inserting a drainage-tube at lower angle of incision, the wound was closed. Drainage-tube removed on the fourth day. Within twenty-four hours after the operation it was evident that the skin and subjacent tissues over the lower part of the back would slough. The healing of the bed-sore kept her in the hospital until January 30th.

March 18th. Reported herself as perfectly well. Has menstruated regularly every four weeks. Duration and amount of flow same as before the operation.

**CASE II.** Cœliotomy: cystoma of ovary, chronic peritonitis.

B. G., single, thirty-four years of age, entered the hospital December 15th. Grandfather died of cancer. Five years ago had an attack of pelvic inflammation, which was followed by an abscess which discharged through the vagina. One year later had a severe attack of peritonitis. Six years ago was told she had an ovarian tumor on the left side. Constant, severe abdominal pain confining her to bed most of the time for the past few weeks. Since last May has been unwell every two to three weeks. Flows six to eight days, and saturates ten to twelve napkins. Severe dysmenorrhœa, confining her to bed and requiring morphine for its relief; frequent headache; poor appetite; constipation; painful micturition, with more or less tenesmus.

December 17th. Examined, under ether, by Drs. Johnson, Kingman and Conant. The uterus was found well to the left, and on the right there was a fluctuating tumor reaching above the umbilicus, and extending along the median line to the left. It bulged into Douglas's cul-de-sac, feeling like a so-called pelvic abscess.

December 20th. Cœliotomy. Dr. Conant assisted. Dr. John G. Blake was present. Abdominal walls very vascular. Dr. Conant, under such a condition of affairs, has observed that adhesions are usually present, and that there is increased vascularity within the abdominal cavity. The cyst was adherent to right parietal peritoneum, and in front and on the left side its wall was covered by adherent omentum and mesentery. An attempt was made to free these adhesions, but the hæmorrhage was so severe, after going a short way, that it was abandoned, and the cyst, having been emptied of two quarts of thick, chocolate-colored fluid, was sutured to the abdominal opening, and drainage-tube inserted. The wall of the cyst was at least one half-inch in thickness. The cyst was washed out twice each day.

December 27th. Discharge from sac sweet, but cavity contained only five drachms of water when filled. This showed that part of the cyst must have been shut off by adhesion of the walls, and the cavity that was closing up was only a small portion of the original cyst.

January 6th. An attack of peritonitis on left side of abdomen. Vomiting, with great pain, for several days.

January 7th. Bulging of abdomen on the left side, just below the umbilicus.

January 17th. Abdomen opened for exploration. Dr. Conant assisted. Incision opened directly into a cavity containing about a quart of bloody serum and pus. This was found to be a part of the old cyst that had been shut off from the first opening and pulled by adhesions over to the left. The cavity was washed out, and drainage-tube inserted. The cavity was washed out twice every day, and by March 1st it was entirely obliterated. Hydrogen peroxide was freely used in this case, and worked admirably. Although still in the hospital, she is up and about, makes her bed, and goes over the stairs. The abdomen is as soft as in the normal condition.

**CASE III.** Cœliotomy: chronic salpingitis and peritonitis.

S. H., single, twenty-four years of age, entered the hospital December 15th. Five years ago fell down stairs. The accident was followed by severe backache. A retroversion was found at that time. After packing for some weeks the uterus was replaced, and a pessary was worn for two years. Two years ago had an abortion performed. This was followed by an attack of peritonitis, and since then she has had more or less pelvic trouble. For ten days previous to entering the hospital she had been suffering from an attack of peritonitis on the right side of the pelvis.

On examination, under ether, by Drs. Conant and Johnson, a mass as large as a small coconut was found in the right side of the pelvis, and felt exactly like an intra-ligamentous cyst. There was no bulging into the vagina. Aspiration resulted in the withdrawal of a clear, serous fluid. In thirteen days the mass on the right side had entirely disappeared. Discharged.

February 26th. Entered the hospital for removal of tubes and ovaries. It was decided to leave the left ovary and tube if they were found healthy.

February 28th. Cœliotomy. Dr. Conant assisted. Abdominal walls were very vascular. Adhesions were found on entering the abdomen bridging over the pelvic cavity in every direction. On the right side the tube and ovary were so firmly imbedded that it seemed best to leave that side alone. On the left side the tube and ovary were removed after a great deal of trouble in separating adhesions from mesentery and omentum. Great difficulty was experienced in stopping bleeding from mesentery, which was of a dark angry-looking color.

Dr. W. F. Whitney reported as follows: "The specimen from the case of S. H. consisted of the ovary and a portion of the tube. The former was of normal size, surface whitish and opaque, and on section numerous small cysts with clear contents were found. The tube was of normal size, slightly tortuous, and covered with adhesions, which passed over on to the ovary. The interior of the tube showed no marked change. The diagnosis is chronic peritonitis and retention cysts of the ovary."

Drainage-tube was inserted and left in thirty-six hours. During the first six hours seven drachms of bloody serum were sucked from the tube, after that only clear serum was obtained. Within eight hours after removal of the tube both temperature and pulse went up, and it was feared that it had been removed too soon. Whiskey was immediately given by the rectum in large doses, and one drachm of sulphate of magnesia was given by the mouth every half-hour. In a few hours the bowels began to move, and in all moved seven times. At once temperature and pulse

dropped, and convalescence was uneventful. Wound healed perfectly.

March 25th. Menstruation has not returned.

CASE IV. Celiotomy: Intra-ligamentous cysto-adenoma.

J. G., married, twenty-nine years of age, entered the hospital January 9th. Amenorrhœa for two and a half years. For two weeks before entering the hospital she had severe pain in the right ovarian region.

January 15th. Operation. Dr. Burrage assisted. A cyst of the right ovary about the size of a large orange, was found growing between the layers of the broad ligament. After separating the layers of the broad ligament the cyst was found to be so adherent that it could not be removed. After emptying it the walls were sewed to the abdominal incision, and a drainage-tube inserted. Within thirty-six hours the pulse was 128 and the temperature 101.8°. No flatus had been passed. Abdomen distended, and patient very restless. I well knew what this meant, and no time was lost in giving twelve ounces of liquid citrate of magnesia, with repeated enemas of turpentine and water. The paralysis of the intestine once overcome, the septic peritonitis would disappear like smoke. Next day bowels had not moved; pulse 120, temperature 101°. Twelve ounces of liquid citrate of magnesia were given, and repeated in four hours. During the day, in addition to two ounces of sulphate of magnesia, sixteen grains of calomel were given. Stercoraceous vomiting was present. In the evening the bowels began to move, and kept moving most all night. Next morning the temperature was normal. For fifteen days the pulse was quite high, due to the presence of the tube as has repeatedly been seen in such cases. On the sixth day the sutures were removed. Union was perfect down to drainage-tube. Seven days after the operation salivation appeared. The gums became swollen and soft, the teeth loosened and the mouth was very sore. It was all of six weeks before the mouth was well. Eighteen days after the operation the cyst had closed so that the tube was pushed out. Excellent results were obtained from the use of peroxide of hydrogen. In five weeks after the operation she was up and about.

March 11th. Discharged at own request. A sinus one inch in depth and the size of a knitting needle still remained in the lower angle of the scar where the tube had been.

April 18th. Sinus almost closed.

September, 1891. Six silk sutures were discharged through this sinus, and then it closed.

CASE V. Celiotomy: Chronic peritonitis.

M. E. M., single, twenty-four years of age, entered the hospital January 12th. Phthisical family history. Four years ago had pleurisy with effusion. Has constant severe pain in lower abdomen, requiring several injections of morphine almost daily. Appetite poor. Bowels constipated. Between four and five years ago consulted a physician for menorrhagia, and an application was made inside the uterus at the first visit. From that she had leucorrhœa, never any before. Soon after consulted another physician for menorrhagia. Electricity was used, and one electrode was passed inside the uterus. Within forty-eight hours after the first application of electricity peritonitis ensued. In July, 1889, had another attack of peritonitis. In February, 1890, had another attack. During this

attack was seen by Dr. R. H. Fitz, and it was his opinion that the peritonitis was of tubal origin. The three attacks were severe. Since the last attack she has been confined to the bed most of the time.

Up to the attack of peritonitis in 1890, menstruated every two to three weeks with profuse flow. Since then has flowed every five to seven weeks, but the amount has been excessive. Has severe abdominal pain one to two days before, and first two days of the flow. She had seen seventeen physicians since the first attack of peritonitis. Ten had advised against, and seven for an operation. Dr. Johnson saw her in consultation with Dr. H. L. Smith, a few months after the third attack of peritonitis. Under ether, the left ovary and tube were found down behind the broad ligament and adherent.

January 14th. Operation. Dr. Conant assisted. Dr. H. L. Smith was present. Both ovaries and tubes were removed. The right ovary and tube, this was the side on which the attack of peritonitis began in February, 1890, were adherent to omentum, mesentery and broad ligament. The left ovary and tube were adherent to omentum and broad ligament. In four days the morphia was stopped and she has taken none since.

Report of Dr. W. F. Whitney, on both ovaries and Fallopian tubes: "Both presented similar appearances although one was rather more marked than the other. The surface was covered by relatively firm fibrous adhesions binding tubes and ovaries together, and completely obliterating the free end of the tubes. The tissue was in general injected with blood. Both tubes were dilated, one much more so than the other. There was a slight hemorrhage into the opening of the tubes with a thickening of the membrane and in places slight granulation tissue. The walls of the tubes were infiltrated with small, round cells. The ovaries contained numerous small retention cysts, but otherwise did not present any abnormal appearance. The diagnosis is chronic peritonitis and salpingitis."

Convalescence was without a drawback. Two months after the operation there had been no return of the abdominal pain. From March 15th she flowed nine days and soaked twenty-four napkins. She was told that the flowing was probably due to hyperplastic endometritis. This condition has been observed in a few cases after removal of tubes and ovaries for chronic peritonitis, coming on a few months after the abdominal operation. Curetting with the application of nitric acid cures the disease.

CASE VI. Celiotomy: chronic peritonitis.

L. T. W., single, thirty-four years of age, entered the hospital January 31st. For the last fifteen years has had poor health. Severe headache and backache. Backache has been the chief trouble. Dysmenorrhœa has been intense for the last four or five years. For the past four or five months the pain has been most marked two days before the flow, continuing with severity throughout. Menstruates regularly every four weeks; flows four to five days; saturates six to eight napkins. Has been able to get out but little during the past year, and has suffered an "immense amount of pain." Poor appetite. Bowels constipated.

February 2d. Operation. Dr. J. W. Elliot was present in consultation, Dr. Conant assisted, Dr. F. F. Whittier was present. After the abdominal cavity had been opened, Dr. Elliot examined the pelvic organs,

and agreed with Dr. Johnson that both ovaries and tubes should be removed. The right ovary was in a pocket formed by adhesions between the right tube and peritoneum covering the posterior surface of the right broad ligament. Left ovary and tube prolapsed into Douglas pouch and adherent.

Dr. W. F. Whitney's report: "Ovaries and tubes varied somewhat in size, the one being a third larger than the other. The surface was smooth, whitish opaque, and here and there were small cysts, with thin, clear, fluid contents to be seen shining through. Upon section, the outer fibrous layer was found to be slightly thickened, and in the cortical layer were relatively few Graafian follicles to be seen. The organ was filled in all directions by numerous white, convoluted cicatrices, and there were numerous smooth-walled cysts varying from the size of a pin's head to a large pea. There were evidences of chronic peritonitis in the form of slight adhesions. It has also suggested itself to me that the swelling of the ovary at the menstrual period may in some way cause pressure on the nerves in the centre, where there are numerous cysts and a thickening of the external fibrous coat."

Convalescence was without a drawback.

CASE VII. Cæliotomy: chronic peritonitis.

A. B. W., single, twenty-six years of age, entered the hospital February 23d. Pthisical family history. Menstruation began at fifteen. Regular up to one year ago, since then has been unwell every twenty-one to twenty-three days. Formerly flowed seven, now flows five days. Severe pain in the lower abdomen first three days of the flow. Unable to exert herself but little, or to do any work, on account of the severe abdominal pains. During the past eighteen months has had several quite severe uterine hemorrhages, brought on by over-exertion. Eighteen months ago had a severe attack of peritonitis. It was three months before she was out of the house. This evidently was the starting point of the severe pelvic troubles.

February 25th. Operation. Dr. Couant assisted, Dr. Bundy was present. On the left side, the ovary and tube were found adherent to the mesentery. On the right, the ovary was found in a cavity bridged over with adhesions, and it was necessary to dig it out with the index-finger. Both tubes and ovaries were removed.

Dr. W. F. Whitney's report: "Specimen from the case of A. B. W. consisted of ovaries and tubes. The former were of normal size, surface smooth, and in no way presented any marked deviation from the normal. The tubes were about normal size; one was slightly larger than the other and a little tortuous. The surfaces of both were covered with thin, highly vascularized adhesions; the fibrinated extremity of one was entirely closed by adhesions, and that of the other partially so. The mucous membrane was slightly thickened and folded, otherwise not abnormal. The changes seem all to be those of a chronic peritonitis."

Sutures removed on the seventh day. Union perfect. Eleven days after the operation a small superficial abscess appeared in the line of incision. With this exception convalescence was uninterrupted.

(To be continued.)

The Algerian Council of War has recently condemned a soldier to death for having struck on the face the surgeon of his regiment who had refused to place him on the sick list.

## A CASE OF DERMATITIS IODOFORMI.

BY ALBERT H. TUTTLE, M.D., CAMBRIDGE, MASS.

Mrs. R., sixty years of age, and a Bavarian by birth, while acting in the capacity of nurse, used iodoform very freely. Within twenty-four hours from the time of its use, a fine eruption consisting of macules, papules and vesicles took place over those parts of the body exposed to the air, namely, the face, neck, hands and wrists.

Soon a diffuse redness united all the lesions, and there was considerable oedema in the parts, more especially the eyelids and back of the hands. The conjunctiva was intensely congested.

The eruption appeared simultaneously in all the parts exposed, but was most severe on the hands and between the fingers, where the contact with the drug was greatest. There was no apparent abrasion of the skin anywhere, through which absorption could have taken place.

Between the fingers the vesicles, which for most part were about one-eighth of an inch in diameter, became more plentiful, in many places becoming confluent, after which the superficial epithelium came away as light colored masses, leaving a red oozing surface behind.

On the fifth day there was some headache, and the urine was tested with nitric acid for ioline, but the result was negative.

Itching was a prominent symptom, and exfoliation of the epidermis occurred over the back of the hands. By using a borax solution for the eyes and carbolized cosmoline on the skin, resolution was rapidly established, during the course of which several large red blotches appeared on the palm of the hands.

The course of the trouble, which was somewhat protracted by the continued exposure of the patient to iodoform during the beginning, was about ten days. The inflammation grew rapidly worse, until recognizing iodoform as the cause of the trouble, its use was discontinued.

On questioning the patient, I found that twice before she had suffered from similar attacks after exposure to iodoform in the treatment of her patients.

## Medical Progress.

### RECENT PROGRESS IN SURGERY.

BY H. L. BURRELL, M.D., AND H. W. CUSHING, M.D.

ON THE EFFECT OF THE DIVISION OF CERTAIN CONSTITUENTS OF THE SPERMATIC CORD IN THE RADICAL CURE OF VARICOCELE AND OTHER OPERATIONS UPON THE VITALITY OF THE TESTICLE.

Dr. WM. H. BENNET has contributed an article of considerable interest regarding the cure of varicocele.<sup>1</sup> The principal points to which Dr. Bennet wishes to call attention may be summed up in the following conclusions, which, of course, are very different from what is commonly taught, but which he believes are perfectly sound:

(1) That the vas deferens having been displaced in the manner usually adopted in operations for varicocele, the spermatic artery does not accompany it, but remains with the spermatic veins. (2) That in cases

<sup>1</sup> Lancet, March 7, 1891, p. 532.

of varicocele the division of the main trunk of the spermatic artery, together with the veins, if the ordinary principles of surgical cleanliness be observed, is not only harmless to the testicle, but probably aids in the ultimate relief of the affection by diminishing the pressure of blood going to the testis at the time when almost all the returning veins are suddenly obliterated. (3) That the division of the vas deferens, spermatic artery, and spermatic veins, which entails a section of apparently the whole cord, is not necessarily followed by sloughing, or even subsequent wasting of the testicle, provided that a perfectly aseptic condition of the wound is maintained.

#### EXCISION OF THE GASSERIAN GANGLION.

William Rose,<sup>2</sup> records a case of removal of the Gasserian ganglion for acute neuralgia, first affecting the inferior division of the fifth nerve, for which he stretched the inferior dental nerve and divided its mental branches, giving temporary relief. The trouble continued, and later he trephined the lower jaw and cut away a piece of the nerve trunk. This produced only temporary relief. A year later the pain returned, and in addition there was severe pain in the right side of the tongue indicating the extension of the trouble to the lingual nerve. He then cut down upon the inferior dental and lingual nerves in the pterygoid region, but this was not satisfactory. Finally the pain returned and implicated the alveolar border of the right upper maxilla and extended to the vertex of the head, showing that the superior maxillary division of the fifth nerve was involved. In accordance with a suggestion of Dr. Ferrier he decided to remove the Gasserian ganglion. This operation he performed in the following manner:

He first removed the upper maxilla in the usual way, and then inserted the pin of a half-inch trephine into the foramen ovale and removed a ring of bone. He then caught sight of the Gasserian ganglion on the petrous bone, passed an aneurism needle gently beneath it without injuring the dura. The patient suffered somewhat from the shock, but on the following day her condition was satisfactory. She, however, complained of heat and pain at the back of the right eye-ball, which was very congested, this increased and resulted in panophthalmitis, necessitating the removal of the eye. Her progress in all other respects was very satisfactory. The neuralgia entirely ceased and had not since returned. He thought that in future, when it was necessary to remove the ganglion, this might perhaps be accomplished without removing the jaw. He extremely regretted the loss of the eye, and was disposed to regard it as accidental and not as a necessary result of the operation.<sup>3</sup>

#### TRANSPLANTATION OF MUCOUS MEMBRANE.

The experimental works of E. Djatschenko has contributed the following data to our knowledge in this subject.<sup>4</sup>

The superabundant fat-tissue from the under side of the transplanted piece must be removed with scissors; still all the submucous cellular tissue must not be cut away, or the conditions for the re-establishment of the blood-circulation in the transplanted piece are less favorable. The piece must be firmly and intimately against its new base; to this end hemorrhage

must be stopped, the clotted blood carefully removed, and the transplanted piece sufficiently pressed against the wound surface. Before transplantation, the piece must be washed off in a warm (37° to 38° C.) six per cent. salt solution. Soaking in this solution for not over one and a half hours will not act injuriously.

The operation should be aseptic, but neither the transplanted piece nor the wound surface should be exposed to the use of strong antiseptic solutions. The transplanted piece must be protected from dessication, and it should, if possible, cover the whole wound surface, as the uncovered portion becomes a scar.

#### THE FINAL RESULT OF LIGATION OF THE AFFERENT ARTERIES IN ENLARGED THYROID.

Professor Rydygier, in Krakau, has treated twenty-one patients suffering from thyroidal disease, by the above method, as introduced and advocated by Wölfler, and has from his personal experience published the following conclusions:<sup>5</sup>

Unilateral ligation of the thyroid arteries is uncertain and insufficient in a majority of cases. Still less successful is the ligation of both superior or of both inferior arteries. Kocher's proposition to ligate the vessels of the opposite side when unilateral ligation has been found unsuccessful, is also unsatisfactory, since the interval between the operations permits the development of collateral circulation to prevent the desired effect. The unilateral ligation is inefficient in fibrous and cystic thyroids. The best results were obtained with medium-sized recent parenchymatous thyroids where the gland tissue was not at all or only slightly degenerated. These were much diminished in size and sometimes returned to normal size. Especially successful were the cases of very vascular tumors. The sequelæ of total extirpation of the thyroid have not been seen after arterial ligation, for as much tissue remains after the diminution in size of the gland, as after bilateral resection.

The writer's report concludes with the histories of his twenty-one cases.

#### A NEW OPERATION FOR SPASMODIC WRY-NECK, NAMELY, DIVISION OR EXSECTION OF THE NERVES SUPPLYING THE POSTERIOR ROTATOR MUSCLES OF THE HEAD.

W. W. Keen, M.D., has devised and performed the following operation in view of the implication of the posterior muscles of the neck which rotate the head in cases of spasmodic torticollis.<sup>6</sup> The operation consists of the following steps:

*First Step.*—The field of operation having been shaved and disinfected, make a transverse incision about half an inch below the level of the lobule of the ear, from the middle line of the neck posteriorly, or even slightly overlapping the middle. This incision should be two and a half to three inches long.

*Second Step.*—Divide the trapezius transversely.

*Third Step.*—Dissect up to the trapezius and find the occipitalis major nerve as it emerges from the complexus and enters the trapezius. In the complexus is an intra-muscular aponeurosis. The nerve emerges from the complexus at a point between this aponeurosis and the middle line, usually about a half inch below the incision, but sometimes higher up, and then enters the trapezius. It is always a large nerve of the

<sup>1</sup> Boston Medical Journal, Nov. 1, 1890.  
<sup>2</sup> American Journal of Surgery, February, 1891, p. 132.  
<sup>3</sup> American Journal of Surgery, 1891, xiv, 1, 7.

<sup>4</sup> Arch. L. Klin. Chir., 1890, xl, 1, p. 806.

<sup>5</sup> Annals of Surgery, January, 1891, p. 44.

size of a stout piece of catgut, and it is easily found if sought for at the right place.

**Fourth Step.**—Divide the complexus transversely at the level of the nerve. This division should be made by repeated small cuts, so as not to cut the nerve which is our guide, after which dissect the nerve still further down from the anterior surface of the complexus, where it arises from the posterior division of the second cervical. Cut, or better, excise a portion of the posterior division before the occipitalis major arises from it, so as to catch the filament to the inferior oblique muscle. This divides the *second cervical*.

**Fifth Step.**—Recognize the inferior oblique muscle by following the sub-occipital nerve towards the spine. The nerve passes immediately below the border of the muscle.

**Sixth Step.**—Recognize the sub-occipital triangle formed by the two oblique muscles and the rectus capitis posticus major. In this triangle lies the sub-occipital close to the occiput. It should be traced down to the spine itself, and be divided, or better, excised. This divides the *first cervical*.

**Seventh Step.**—An inch lower down than the occipitalis major, and under the complexus, is the external branch of the posterior division of the third cervical to the splenius. When found it is to be divided or excised close to the bifurcation of the main trunk. This divides the *third cervical*.

A drainage-tube and horse hairs are to be inserted, and as the patient lies on the back, although the wound is very deep, the condition is most favorable for good drainage. If desired, the posterior muscles can be united by buried sutures, independently of those in the skin. The after-treatment is the same as for ordinary operations.

#### AN IDEAL CHOLECYSTOTOMY IN TWO STAGES.

In order to avoid the undesirable sequelae of the usual operation, namely, fistula, Wölfler has modified the operation with a satisfactory result, by opening the gall-bladder extra-peritoneally in the usual way; then the bladder is sutured, and when healed finally, is dissected from its attachments, dropped into the abdominal cavity, and the opening in the abdominal wall closed by suture, as in a laparotomy. Senger is reported as having operated in a similar manner in one case.<sup>7</sup>

#### CONTUSIONS OF THE ABDOMEN.

M. Moty<sup>8</sup> has made a careful study of contusions of the abdomen with special reference to injuries from horse-kicks.

He divides the cases into three classes: the light, the medium and the grave. In the first class he includes contusions in which the intestines and other important organs have escaped injury, and is diagnosed by the progressive disappearance of the symptoms of the shock, and the absence of signs of perforation and extravasation. The second class includes those cases which present some complication, as acute general peritonitis, rupture of a large vessel or of important viscera, and require treatment for from two to three weeks. The third class includes those where a rupture or extensive laceration of the intestines has taken place. The prognosis in all these cases should always be reserved for several weeks on account of the possibility of the development of peritonitis.

He arrives at the following conclusions:

(1) Horse-kicks of the abdomen in many cases produce grave lesions of the intestines.

(2) These lesions are perforations produced in three ways: by rupture, by crushing, and by laceration.

(3) The diagnosis of perforation can often be established by the acute pains resulting after the injection of fluid.

(4) Large perforations and ruptures demand laparotomy and intestinal suture.

(5) This operation may be successfully performed notwithstanding the presence of peritonitis.

(6) Exploratory laparotomy for diagnosis is not permissible. The expectant plan of treatment is always indicated in case of doubt.

(7) The prognosis of contusion of the abdomen should be reserved for a month, in view of the complications which may result.

#### THE TREATMENT OF PENETRATING GUNSHOT WOUNDS OF THE ABDOMEN.

This is a subject which is still open to discussion, and William B. Coley,<sup>9</sup> has contributed an extremely interesting and valuable article on this subject. In one sense it is an answer to an article by M. Reclus and M. Nogués in the *Revue de Chirurgie* of February, 1890, which makes a vigorous attack upon the so-called American method of treating gunshot wounds of the abdomen, and advocates their treatment by the old "laissez-faire" principle.

Dr. Coley has collected 165 cases treated by laparotomy, and has made a careful analysis of the cases. He considers the value of the so-called infallible hydrogen gas test, and notes the following objections to the test: (1) The test is not an "infallible" index of the condition of the alimentary canal. (2) The danger of producing infection of the peritoneal cavity. (3) It shows nothing as to the condition of other viscera, wounds of which "frequently" demand operative interference. (4) It prolongs the operation, interferes with respiration; adds to the shock. (5) It increases the liability of the sutured wounds to give way.

Of the total number, 165, there were 51 recoveries and 114 deaths, giving a mortality of 67.2 per cent. Of this number there were 81 cases of wounds of the "small" intestine, with 25 recoveries, or a mortality of 67.5 per cent; 24 cases of wounds of stomach, six recoveries, mortality 75 per cent; 36 cases of wounds of colon, 12 recoveries, mortality 66.6 per cent; 19 cases of wounds of liver, eight recoveries, mortality 58.7 per cent; 11 cases of wounds of kidney, one recovery, mortality 90.9 per cent; 50 cases, carefully analyzed, showed a mortality of 66½ per cent. for wounds of the small intestine uncomplicated with other visceral injuries, and 70 per cent. when other viscera were wounded.

Wounds of the stomach, liver, and colon all showed the same mortality in *uncomplicated* cases, 66½ per cent.

In the 81 cases of wounds of the small intestine there were 439 perforations, or an average of 5.4 for each case.

Laparotomy was performed in nine cases in which no viscera were wounded; of these nine cases, six made prompt recoveries, and in two of the fatal cases

<sup>7</sup> Schmidt's Jahrb., des gesammten Med., 1891, Bd. 229, p. 181.

<sup>8</sup> *Revue de Chirurgie*, No. 11, 1890, p. 878.

<sup>9</sup> *American Journal of the Medical Sciences*, vol. ci, No. 3, March, 1891, p. 215.

the operation was delayed until the fourth and sixth days, and then performed with the patient *in extremis* for septic peritonitis.

There were 25 cases in which the alimentary canal was found intact; of these, 12 recovered and 13 died; mortality 52 per cent. (this includes many of the fatal kidney cases); 16 cases of resection, three recovered.

Hydrogen-gas tests were used in 13 cases; of these, 11 died, two recovered; mortality 81 per cent. (The test was used in one other case in which operation was not resorted to, and patient recovered.)

Of the total 165 cases, in only nine instances did the operator fail to find all the perforations. In 48 cases, where the causes of death were given, 25 were assigned to septic peritonitis, 19 to shock, 4 to hæmorrhage. In 16 cases, where drainage was used, six recovered and 10 died; mortality 62.7, slightly below the average.

Dr. Coley draws the following conclusions from the above statistics.

Given a shot-wound of the abdomen, the indications are: (1) *Exploratory incision* in the region of the wound to ascertain whether or not it is penetrating. (2) If penetrating, *median laparotomy* as soon as possible after the injury has been received unless suffering from severe shock. (3) Signs of peritonitis, just beginning or well developed, while diminishing the chances of success, are by no means a contra-indication for operative interference.

#### PROLAPSE OF THE RECTUM.

Dr. Vernieuil proposes to overcome this condition by a new procedure which has for its object the elevation and attachment of the rectum to the region of the coccyx, rather than a narrowing of the lower portion of the bowel.<sup>10</sup> The operation is performed as follows:

After reposition of the prolapsed portion, with the patient in the lithotomy position, two incisions, from four to five centimetres in length, are made, at right angles to the long axis of the anus, from the opening of the latter in an outward direction. From the point where these incisions terminate, two other incisions pass to meet each other at the point of the coccyx, thus including an equilateral triangle with its base placed anteriorly. This triangular flap is loosened from behind forward, and left temporarily attached to the tissues surrounding the anus, comprehending in its thickness the skin, the subcutaneous cellular tissue, together with the fibres of the external sphincter. With this flap strongly retracted by means of blunt retractors, the posterior wall of the rectum is loosened for a breadth of from five to six centimetres, and to a height corresponding to the distance from the anus to the tip of the coccyx. Four threads are now passed transversely through the posterior rectal wall, parallel with each other, and not including the rectal mucous membrane. The upper one of these sutures is placed at a point in close relation to the point of the coccyx, while the lower one is removed about fifteen centimetres from the anus. By means of a needle with an eye at the point, which is passed through the skin from without, the threads are drawn through the points of emergence of their respective ends, being selected at about four centimetres from the median lines at either side. The upper suture should be on a level with the articulation between the first bone of the

coccyx and the sacrum, and the lower at about the point of the coccyx; the intervening sutures are placed about equi-distant between. These are now secured upon one side in such a manner that the first and second, and the third and fourth are tied together; rolls of iodoform gauze being placed beneath the loops to prevent the latter from being buried with the skin, strong traction upon these secures the rectum in its new position, and the other ends of the thread are similarly secured. The triangular-shaped flap is now removed, the muco-cutaneous anal margin being preserved, and after inserting a drainage-tube, the wound is closed by sutures.<sup>11</sup>

#### THE TREATMENT OF COMPLETE PROLAPSE OF THE RECTUM.

Harrison Cripps<sup>12</sup> believes that while it may be necessary for the cure of complete prolapse of the rectum, occasionally to resort to complete excision, that, as a rule, the use of lineal cautery is founded upon sound physiological principles attended with very slight risks.

"Since prolapse is due to the slipping of one coat of the bowel on the other, together with want of sufficient rigidity in its walls to prevent invagination, the binding the muscular and mucous coats together, and at the same time stiffening the walls by inflammatory deposit, would seem to be plainly indicated. An exudation artificially produced in the submucous tissue meets this indication by cementing the coats firmly together, thus effectually preventing slipping, and at the same time giving the bowel sufficient rigidity. The actual cautery is admirably fitted to produce an abundant inflammatory exudate. Before performing the operation the bowels should be thoroughly emptied. The patient should be anesthetized and placed in lithotomy position. If possible, the prolapse should be made to protrude; four lines of cautery are then drawn along the bowel in its long axis. These lines should begin well within the canal of the bowel at the apex of the protrusion and terminate at the anal margin; they should be about one-quarter of an inch in width, and deep enough to thoroughly sear but not actually destroy the mucous coat. Where the cautery lines cross large veins these should be tied on each side by passing a threaded needle beneath and knotting. If much time is spent in the operation swelling will take place and the reduction will be difficult.

"In case the prolapse cannot be made to protrude, the bowel may be cauterized *in situ* by using the duck, bill speculum, which may be shifted when necessary. The actual cautery is most satisfactory, since Paquelin's instrument is too hot when first applied and loses heat too readily. After operation a thick india-rubber tube one-third of an inch in calibre and seven inches in length is passed into the bowels for five inches. Strips of oiled lint are then packed around the tube, extending as far as possible into the bowel. Cotton-wool well dusted with iodoform is finally packed into the tube and in and about the anus; thus firm support is given and at the same time the escape of flatus is not prevented.

"Special care must be taken to prevent the descent of the bowel during the early stages of healing. In forty-eight hours the first dressing is removed, the parts are washed, and a clean dressing is applied.

<sup>10</sup> *Annals of Surgery*, March, 1891, p. 218.

<sup>11</sup> *Lancet*, vol. II, No. 15, 1890; *American Journal of the Medical Sciences*, vol. 61, No. 5, May, 1891, p. 616.

After the first few days the dressing can be dispensed with, but the tube is retained for ten days. During this time the bowels should be kept locked by small doses of opium. Evacuation is finally accomplished by means of castor oil and enemata. The patient must not be allowed to strain, and must empty the bowel while lying on his side with the anus drawn a little from the middle line. This should be enforced for at least six weeks, during which time the consolidation is taking place."

(To be continued.)

## Reports of Societies.

### AMERICAN SURGICAL ASSOCIATION.

TWELFTH ANNUAL MEETING HELD IN WASHINGTON, SEPT. 22-25, 1891.

(Continued from No. 14, page 359.)

#### WEDNESDAY. — SECOND DAY.

ASEPTIC AND ANTISEPTIC DETAILS IN SURGERY, by DR. A. G. GERSTER, New York.

Personal cleanliness and cleansing of the field of operation are to be accomplished by mechanical measures rather than by disinfectants. The dirt and oily matter of the skin is removed by emollient potash soap and stiff brush. This is followed by the germicidal lotion. The hands of the surgeon may be sterilized in the following manner: The nails are trimmed short, the hands scrubbed with soap and brush in hot water for one minute. The nails are then cleaned and the hands immersed in strong alcohol and then washed in 1:1000 corrosive sublimate solution. Brushes require careful attention. They may be sterilized by boiling in for five minutes in water containing one per cent. of washing soda. They should be kept in 1:1000 bichloride solution.

Instruments are sterilized by boiling for five minutes in soda solution, in a covered vessel. The addition of the soda prevents formation of rust.

Dressings are rendered absorbent and sterilized by steam. Strong antiseptic agents in dressings are objectionable from their action on the skin. Dressings may also be sterilized by boiling in soda or potash lye.

The use of Florida sponges was recommended as owing to their cheapness they can be used once and then thrown away. Boiling of sponges is to be condemned. Sponges are best prepared by heating followed by immersion in dilute muriatic acid, as it is removed by washing; then immersed in water for ten days to permit the spores to germinate. Each sponge is then kneaded in hot water for one minute with potash or soft soap. They are then placed in five per cent carbolic solution for twenty-four hours. As a substitute for the large flat sponges used in laparotomy he recommended the substitution of pads of absorbent gauze.

In operating, few instruments, sponges and assistants should be employed. The dissection should be clean, the tissues being cut rather than torn. Irrigation should not be employed except when special indications are present. In the abdominal cavity irrigation was condemned. When the peritoneal cavity is contaminated by pus, etc., simple wiping away of the matter is sufficient.

In perfectly aseptic operations, no drainage is re-

quired. Iodoform gauze can often be substituted for the use of tubes. Drainage by tubes is required where there is progressive suppuration.

In combating septic morbid processes, mechanical measures, such as incision, drainage and irrigation are of more importance than chemical measures.

DR. J. COLLINS WARREN, Boston, described the details of operative surgery as practised in the Boston City Hospital, the Massachusetts General Hospital, and the Children's Hospital.

DR. J. WILLIAM WHITE, Philadelphia, thought the time had not yet arrived when the use of antiseptics could be dispensed with. He preferred an antiseptic dressing in all cases except where the wound is absolutely sterile, and where no discharge is to be expected. While in a general way he agreed as to the value of mechanical measures in cleansing the skin he saw no good reason for throwing aside entirely the use of the weaker chemical solutions. There are so many cases in which we cannot be sure that the wound is aseptic, antiseptic dressings become of importance. He had tried the gauze substitute for sponges in abdominal work, but had found it objectionable from the fact that when the gauze remains long in contact with the intestines, threads of the gauze adhere to the intestines.

DR. JOSEPH RANSOHOFF, Cincinnati, said that in some cases it was absolutely impossible to render the part aseptic, and cited cases illustrating this point. In cases where it became clear that the wound is infected, he removes the dressings and soaks the part in hot water. He had discarded the use of sponges altogether. In the majority of cases he employs the aseptic dressing, but could see no harm in the use of antiseptic dressings. Dressings, etc., in private practice may well be sterilized by heating in the oven. He thought that tight closing of the wound should be practised oftener than it now is. Drainage is rarely used except in wounds already septic. He often uses catgut for drainage. In the septic cases he thought that probably the surgeon was often responsible for the infection of the wound. By clean incisions, cutting far away from the disease, and by not using the sharp spoon too freely, infection of the wound in suppurating cases can often be prevented.

DR. E. M. MOORE, Rochester, asked what objection was there to irrigation? In amputations for instance, irrigation with 1 to 1000 bichloride solution affords a ready means of removing clots, etc. The clots are removed and the wound can be left in a dry state. If this irrigation does no harm, why not use it? Dr. Gerster had condemned it, but he had not given his reasons for such condemnation. In certain cases of abdominal section, where there was oozing of blood, hot irrigations of aseptic water were of great service.

DR. GERSTER, in conclusion, said that he did not condemn antiseptic methods. He employed both methods. In its proper place asepticism is infinitely superior to antisepticism, but the cases must be properly selected. Teachers must be careful not to go too far in advance of the rest of the profession. Those who have not learned the detail should be warned to stick to the older methods and working up the higher methods.

#### THE SURGERY OF THE SPINE,

by J. WILLIAM WHITE, M.D., Philadelphia.

The conditions discussed were: congenital deformi-

<sup>1</sup> See page 367 of the Journal.

ties, tuberculosis of the spine, neoplasms and traumas. Under this first head, *spina bifida* is the only condition requiring consideration. In this, injection by an iodo-glycerine solution offers the greater prospect of ultimate recovery with the least immediate danger.

In tuberculosis of the spine the indications for interference are the evacuation of pus, removal of a sequestrum or of a focus of carious bone, and relief of the cord from pressure. There are records of 14 operations upon the bodies of vertebrae for abscess, with eight cures, five cases improved and one death, which had no relation to the operation. There have been 40 cases of operation on the spine for the relief of pressure. In 22 there was either improvement or cure. The effect of suspension in the treatment of Pott's paralysis has been so favorable that it should occupy a prominent position.

Conclusions in regard to operative treatment of spinal tuberculosis with symptoms of pressure on the cord, were:

(1) The paralysis in Pott's disease is not, as a rule, due to a transverse myelitis or hopeless degeneration, and is not usually due to the pressure of the carious or displaced vertebrae; but is in the majority of cases the result of an external pachymeningitis, which results in the formation of an extra-dural connective tissue tumor.

(2) Speaking generally, a favorable prognosis is to be given, especially in children, in cases of Pott's paralysis, in which the abscess, if any exists, can be evacuated; the treatment by extension and with plaster jacket can be employed, and the patient can be put under the most favorable hygienic conditions.

(3) In cases in which all this has been tried unsuccessfully, or in those in which disease is slowly but steadily progressing to an unfavorable termination; where with more or less complete loss of motion and sensation below the level of the lesion, there are incontinence of urine and feces and the development of bed-sores, and especially where acute symptoms threaten life, resection becomes justifiable.

(4) Operation having been decided upon for any or all of the above reasons, the prognosis will be favorable in direct proportion to the youth and strength of the patient, the absence of generalized tuberculosis and the nearness of the lesion to the base of the sign.

(5) When the tuberculous process affects the arches and there is paraplegia, we may sometimes operate, hoping not only to free the cord but at the same time remove the focus of disease. This double indication may also be fulfilled in those cases where without bony disease there is posterior pachymeningitis or a tuberculoma occupying the canal.

(6) If the lesion of the bodies of the vertebrae is in the lumbar region at a point where these bodies are accessible, it might be possible in certain cases to expose the cord from the back, by removal of the laminae, with the object not only of removing pressure but of reaching and taking away the diseased bone and tubercular granulation.

(7) In tuberculosis of the body of a vertebra and compression of the cord by anterior pachymeningitis we can fulfill only one indication—liberate the cord from pressure. We should operate only in grave cases where acute compression, the appearance of respiratory complications, the rapid development of degenerative processes force us to interfere, or where the course of a chronic case is steadily toward a fatal

termination although no advanced visceral tuberculous lesions are present.

In regard to neoplasms, it was said that every case of focal spinal lesion, thought to depend on a tumor and not distinctly a malignant and generalized disease, should be regarded as amenable to operative interference, no matter how marked the symptoms of pressure may be, nor how long continued.

**Traumatism.**—The indications and contra-indications for trephining in spinal fractures are based on the following points: (1) the nature of the vertebral lesion and the nature and extent of the medullary lesion; (2) the time which has elapsed since the traumatism; (3) the regional level of the medullary lesion.

The following conclusions were presented:

(1) Some objections urged against operative interference in spinal traumatism, that is, hemorrhage, frequency of absolute destruction of the cord, pressure from inaccessible fragments of bone, etc., have been shown to be unsupported by clinical facts; others were largely due to a well-founded dread of (a) the shock, in those cases operated on in pre-anæsthetic times, and (b) consecutive inflammation, suppuration and pyæmia in pre-antiseptic periods.

(2) Some results of recent operative interference in properly selected cases of fracture of the spine are encouraging, and should lead to the more frequent employment of resection of the posterior arches and laminae: (a) in all cases in which depression of those portions either from fracture or dislocation is obvious; (b) in some cases in which, after fracture, rapidly progressive degenerative changes manifest themselves; (c) in all cases in which there is compression of the cauda equina from any cause, whether from anterior or posterior fracture or from cicatricial tissue; (d) in the presence of characteristic symptoms of spinal hemorrhage, intra or extra medullary.

(3) Operation is contra-indicated by a history of such severe crushing force as would be likely to cause disorganization of the cord. The question which will remain in doubt previous to operation will usually be that of the extent of damage done to the cord and the possibility of its taking on a reparative action. As to this, the safest rule is that which has been formulated by Lauenstein, namely, that if after the lapse of six or ten weeks there is incontinence of urine or incontinence of feces, and especially if there is also the development and spreading of bed-sores, but little is to be hoped for from the unaided efforts of nature. If, however, these symptoms are absent, and if there be the least improvement it will be proper for the surgeon to wait operative interference still longer.

DR. H. H. MURPHY, of St. Louis, dwelt upon the importance of remembering the liability of severe shock in these spinal operations. He reported three cases of bullet wounds of the spinal column, one of which ended fatally.

DR. JOHN B. ROBERTS, Philadelphia, insisted that injuries and diseases of the spine of a surgical kind, should be treated as we treat injuries of the cranial cavity. Cases of Pott's disease with angular curvature have been referred to, but sufficient stress has not been laid upon the fact that many of these cases with motor paralysis improve under ordinary remedies, the inflammatory exudation being absorbed. In traumatism of the spine, we should explore the spine as we should the brain. In severe injuries with fracture spicules of bone are often driven down on the cord.

DR. J. J. PUTNAM, of Boston, thought that the dangers of inflammation had not been sufficiently dwelt upon. Some cases of spinal injury, after one to four years, show some improvement. In such cases an operation may add to the improvement.

DR. JAMES M'CANN reported two cases of spinal injury in which operation had been performed. In one, death followed. In the other, there was great improvement.

#### THE TREATMENT OF TUBERCULOSIS OF BONES AND JOINTS BY PARENCHYMATOUS AND INTRA-ARTICULAR INJECTIONS.

by DR. N. SENN, Chicago.

The following conclusions were presented:

(1) Parenchymatous and intra-articular injections of safe antibacillary substances are indicated in all subcutaneous tubercular lesions of bones and joints accessible to this treatment.

(2) Of all substances, so far employed in this method of treatment, iodoform has yielded the best results.

(3) The curative effect of iodoform in the treatment of local tuberculosis, is due to its antibacillary effect, and its stimulating action on the healthy tissue adjacent to the tubercular product.

(4) A ten per cent. emulsion in glycerine or pure olive oil is the best form in which this remedy should be administered subcutaneously.

(5) The ethereal solution should never be employed as it is liable to cause necrosis of the tissues overlying the abscess or iodoform intoxication.

(6) Tubercular abscesses and joints containing synovial fluid or tubercular pus should always be washed out thoroughly with a three to five per cent. solution of boracic acid before the injection is made.

(7) Injections should be made at intervals of one or two weeks, and their use persisted in until the indications point to the cessation of tubercular inflammation and the substitution for it of a satisfactory process of repair, or until the result of this treatment has shown its inefficacy and indications present themselves of the necessity of resorting to operative interference.

(8) If the treatment promises to be successful, symptoms pointing to improvement manifest themselves not later than after the second or third injection.

(9) In tubercular empyema of joints and tubercular abscess, gradual diminution of the contents of the joint or abscess at each successive tapping, and lessening of the solid contents of the fluid and increase of its viscosity, are the conditions which indicate unerringly that the injections are proving useful, and that in all probability a cure will result from their further use.

(10) Moderate use of the limb is compatible with this method of treatment, provided the disease has not resulted in deformities, which would be aggravated by further use of the limb. In such cases correction of the deformity should be postponed until the primary joint affection has been cured by the injections.

(11) Parachymatous and intra-articular medication with antibacillary material, has yielded the best results in tubercular spondylitis attended by abscess formation and tuberculous of the knee and wrist joints.

(12) This treatment may prove successful in primary osseous tuberculosis followed by involvement of the joint, provided the osseous foci are small.

(13) Extensive sequestrums of articular ends with secondary tubercular synovitis, always necessitates resection, but preliminary treatment by iodoform injection

into the affected joints constitutes a valuable preparatory treatment to the operation, and adds to the certainty of a favorable result.

(14) In open tubercular affections of joints, incision, scraping, disinfection, iodoformization, iodoform gauze tampon, suturing, and subsequent injections of iodoform emulsion is advised, and yields excellent results, and should be employed in all cases in which a more formidable operation can be avoided.

(15) Balsam of Peru ranks next to iodoform in the treatment of tubercular affection of bones and joints; and if the latter remedy for any reason cannot be employed, or has failed in effecting the desired result, it should be given a fair trial, if operative treatment is not urgently indicated.

#### THURSDAY. — THIRD DAY. — EXECUTIVE SESSION.

The officers for the ensuing year are as follows: President, Dr. Phineas S. Conner, Cincinnati; First Vice-President, Dr. L. McLane Tiffany, Baltimore; Second Vice-President, Dr. Levi C. Lane, San Francisco; Secretary, Dr. J. R. Weist, Richmond, Ind.; Recorder, Dr. J. Ewing Mears, Philadelphia; Treasurer, Dr. John B. Roberts, Philadelphia; Member of Council, Dr. Claudius H. Martin, Mobile.

The committee recommended the following resolution, which was adopted: "Resolved, that the Association hereafter hold each triennial meeting at Washington, and that other annual meetings be held at such time and place as the Association may name."

Next meeting will be held in Boston, in June, 1892.

The following were elected to membership: Drs. J. S. Wight, Brooklyn, George R. Fowler, Brooklyn, N. Y.; Dr. E. W. Walker, Cincinnati, O.

The following honorary members were elected: Mr. John Chiene, Edinburgh; Mr. Reginald Harrison, London; Mr. Thomas Bryant, London; Mr. Arthur Eduard Durham, London.

#### REGULAR SESSION.

##### RECURRENCE OF CANCER OF THE BREAST.

by FREDERIC S. DENNIS, M.D., New York.

Only those cases were included in which a microscopical examination of the tumor had been made. The necessity of an investigation of carcinoma of the breast is shown by the fact, that, in England alone, 7,000 deaths occur annually from carcinoma and a large proportion of these are cancer of the breast. It has been demonstrated that cancer is a disease which is slowly increasing in civilized nations. A study of the subject shows that there are seventy-five per cent. of recurrences. These include cases of incomplete operation, that is, where the axilla has not been opened. In the primary growth at the beginning, the neoplasm is of local origin. Early and complete removal of the growth relieves the local disease, but the operation does not relieve the predisposition or susceptibility or the capability for the recurrence of the disease. It is possible that the capability is limited to a certain extent.

The recurrence of carcinoma of the breast is influenced, first, by the period of time from the appearance of the growth to the date of the operation. In the cases of the author in which the cure had continued for three years or more, the tumors were removed on an average six months from the date of their first recognition in the breast. In all the cases of permanent cure, the axillary glands were not invaded.

Recurrence is influenced, second, by the extent to which infiltration has taken place by any one or all of the three well-recognized ways of dissemination. When the tumor has existed long enough to show extension in these directions, the growth has been of long duration.

Third, recurrence is influenced by the radical character of the operation itself. Complete removal of the breast is essential. The method of Mr. Stiles, of Edinburgh, by which the tumor after removal is treated with dilute nitric acid, in order to show whether or not the incision has been made in healthy structures and all the diseased structure has been removed, was described. The reported mortality of the operation is high, but, in the author's seventy-one cases, there had been but one death and that was from continued bleeding in hæmophilia. In operation, not only the breast, but the axillary glands were removed in most cases.

Fourth, recurrence is influenced by the histological character of the carcinoma itself. Where the structure differs slightly from the normal the clinical history is favorable. In none of these cases was there recurrence. Where there is great departure from the normal type, the clinical history is unfavorable. The more embryonic the structure the greater the chance of recurrence.

Fifth, the recurrence is influenced by the simultaneous occurrence in both breasts. This occurs in five per cent. of the cases. These patients are very liable to recurrence.

Sixth, recurrence is influenced by the personal factor of the individual, such as age, sex, marriage, fecundity, sterility, pregnancy, traumatism, heredity, menstruation, metastasis, mental condition, locality, etc.

Seventy-one cases of carcinoma of the breast which had been operated on, were referred to. In one there had been death from hæmophilia. In nearly all the axilla was opened. The operation consisted of excision of the entire breast, with all contiguous skin, the para and peri-mammary, fatty areolar tissue, the pectoral glands, the pectoral fascia and also removal of the axillary glands and fatty axillary tissue. In some cases the supra-clavicular glands were removed, and in one case excision of the ribs was done. The percentage of permanent cures amounted to thirty per cent. The author held that with early and radical operation, recurrence of carcinoma of the breast will be comparatively rare.

MR. THOMAS BRYANT, London, believed firmly in the local origin of carcinoma, although we must admit that there may be a predisposition on the part of the patient to the development of the disease. The disease should be treated at an early period and this brings us to the question of diagnosis. Many cases do not come under observation until the disease is well advanced, because the patient imagines that a disease unassociated with pain cannot be cancer. Where induration appears in a breast during the period of functional activity, there may be some hesitation in the diagnosis, but, in one-thirty cases of this kind, he had recommended immediate operation and in all the cases the disease was shown to be malignant. In none has recurrence taken place. When the disease has advanced somewhat but without dimpling and puckering of the skin and some immobility, we may get a good result by making a thorough operation. He had had some cases without recurrence for from five to twenty years. In the more advanced cases the surgeon should limit his operation to those in which there was a reasonable

prospect of removing all the diseased structure. He does not remove the axillary glands in every case. If the glands be enlarged or the disease extend upward in that direction, he removes the glands thoroughly. Where the disease is quite local and there is no evidence of axillary involvement, the axilla is not opened. In the atrophic form of cancer he thought it better not to interfere unless the tumor was giving rise to great inconvenience. Operation in these cases is often followed by a more rapid form of growth. Again, in this form of cancer where the lymphatics can be traced distinctly and the breast has a brawny feel — the lymphatic form of cancer — the surgeon does no good by interference.

SIR WILLIAM MACCORMAC, London, thought that the axilla should be opened in operations for carcinoma of the breast for two reasons, namely, an examination of 117 cases of cancer of the breast showed that in all but two there was axillary involvement, and second, in ninety per cent. of the recurrence, the disease appears in the axilla.

DR. LEWIS S. PILCHER, Brooklyn, thought that the term "recurrence" was not applicable to many of these cases, and that in many the disease was simply a continuance of the former growth. If the case goes one year without the appearance of a return of the disease, it may be considered that the disease has been removed, and if it appears later it can be regarded as a recurrent, a renewed or a new attack of cancer. In every case of cancer there is a predisposition to the disease and we should search for some agent to counteract this constitutional predisposition, which we can use in addition to operative measures. Arsenic has for many years been used for this purpose. Dr. Wight, of Brooklyn, has suggested the use of carbonate of lime for the same purpose.

DR. L. McLANE TIFFANY, Baltimore, did not think that we could set any limit to the time at which recurrence might take place. He had had the disease return eight years after operation. He was a firm believer in the local origin of cancer. The date at which the disease is recognized varies much. In some the disease came before the surgeon shortly after its commencement, while in others the tumor had reached considerable size. The time at which the disease is discovered by the patient bears no relation to the time of its commencement. Too much stress had not been laid in the necessity of thorough operation. In only two cases out of eighty operations for cancer of the breast had he found the axillary glands not enlarged. The pectoral fascia should be removed, and at times a portion of the muscle should be cut away.

DR. KINGSTON, Montreal, believed that cancer was essentially a local disease. If we believe this, operation should be done at as early a date as possible. The glands should be removed not only from the axilla, but from its neighborhood if they are enlarged; but this should not form a necessary part of the first operation. Such a procedure adds greatly to the discomfort and to the danger. Where there is the slightest suspicion of involvement of the glands, they should be removed. If there should be recurrence, the operation should be repeated as often as circumstances seem to warrant.

DR. JOSEPH RANSONOFF, Cincinnati, reported thirty cases of removal of the breast for cancer, without a death. He thought that the danger of the operation was not materially increased by opening the axilla.

DR. C. B. NANCREDE, Ann Arbor, said with reference to the three-year limit, that this had been proven to exclude 98 per cent of the recurrences. It is impossible to tell whether or not the axillary glands are involved without opening the axilla. Unless this is done the majority of the cases will be left unbenefited. He advised that the axilla be opened first, and if the glands could not be removed to close the wound and not remove the breast.

DR. J. R. WEIST, Richmond, Indiana, had operated fifty-five times for cancer of the breast, and makes it a rule to open the axilla in every case.

DR. GEORGE W. GAY, Boston, felt that there was no such thing as a local origin of cancer as we have the local origin of a fatty tumor. When it can be shown that a cancer taken out will not return, just as a fatty tumor when removed does not return, then we can prove the local origin of carcinoma.

DR. EDWARD M. MOORE, Rochester, always operates in as thorough a manner as possible. He always opened the axilla, and did not think that it added to the risks of the operation. He did not agree with Mr. Bryant in regard to the atrophic cases in old individuals. In these, he recommended operations, considering recurrence very improbable. He reported one case living seventeen years after operation, and now seventy-nine years of age.

#### A CASE OF DIFFUSE FIBROMA WITH A TENDENCY TO INTRA-CANALICULAR GROWTH OF BOTH BREASTS.<sup>1</sup>

by DR. C. B. PORTER, of Boston.

Mrs. M., thirty-seven years of age, resident of Nova Scotia, was admitted to the Massachusetts General Hospital. Has had two children, the youngest ten years old. Three years ago she discovered a hard lump in the right breast, which gradually increased in size. Three months later the right breast commenced to enlarge. The breasts continued to slowly enlarge until three months ago when a rapid increase took place, and the breasts soon became burdensome by their size and weight. On examination, she was found to be pale, emaciated and with ovarian facies. Right breast: largest circumference 38 inches, length from chest wall to nipple 17 inches, circumference of base 23 inches. Left breast: largest circumference 28 inches, length from chest wall to nipple 14 inches, circumference at base 23 inches. Throughout both breasts were felt movable barded masses of irregular outline, varying in size from an orange to a closed fist.

It was decided to remove the left breast first. The breast was transfixed at the base with two skewers, and constricted below this with a tightly drawn rubber tourniquet. The breast was then removed, and but little blood lost. Three weeks later the right breast was removed. Twenty days after the second operation the patient was permitted to leave the hospital to visit friends, but instead she went home, requiring a long sea journey. A week later she developed erysipelas. This had much improved in four days when she suddenly aborted a five months' fetus.

The weight of the right breast after removal was 43 pounds, and that of the left 17 pounds, a total of 60 pounds. A *résumé* of the reported cases was added.

DR. J. M. BARTON, of Philadelphia, reported a similar case, on which he had operated, and in which one breast was involved.

(To be continued.)

#### ASSOCIATION OF AMERICAN PHYSICIANS.

THE SIXTH ANNUAL MEETING, HELD IN WASHINGTON, SEPT. 22-25, 1891.

TUESDAY. — FIRST DAY.

At the opening of the session, the President, Dr. WILLIAM PEPPER, of Philadelphia, delivered an

ADDRESS.<sup>1</sup>

Dr. Pepper spoke first of the members who had died during the past year. Hosmer Allen Johnson, a founder, trustee and professor of the Chicago Medical College, and one of the original members, died February 26, 1891, at the age of sixty-eight years. In the truest sense of the word, he was an ornament to our profession. Dignity and elevation of character, blended with rare charm of presence, conferred additional distinction upon his high scientific and literary attainments.

James Kingsley Thacher, professor of physiology in the Medical Department of Yale University, and an original member of the Association, died on April 20, 1891, at the age of forty-four years. Dr. Thacher early displayed rare powers as an investigator and thinker. It was not until the age of thirty-three and after he had won international distinction by his researches in comparative anatomy and physiology, that he began the practice of medicine. He rapidly attained the front rank of the profession. He well illustrated the highest type of the physician—the student of Nature as revealed in the functions and disorders of the human body.

Richard Lee MacDonnell, professor of clinical medicine in McGill University, had been a member of the Association but a short time when his death occurred on July 31, 1891, at the sadly early age of thirty-five years. He possessed gifts and ability of high order as a clinician, as a writer, and as a teacher.

Dr. Fordyce Barker, one of the Honorary Members, died May 30, 1891, at the age of seventy-three. His long life seemed all too short for the countless acts of courtesy and charity which he found place for in a career rich in professional and social success. The affectionate solicitude with which he lavished on his patients, rich and poor alike, the resources of his skill, made him one of the most successful and beloved of physicians.

In the death of Joseph Leidy, which occurred on April 30, 1891, at the age of sixty-eight years, the medical profession in America lost its most loved and honored member, and American science its most illustrious representative. Leidy never had a theory to support or a purpose to serve. The all-sufficing motive of his life was to learn the truth of Nature, and to help others to learn it also. He made great discoveries in various fields of scientific research; but he never seemed to feel any credit was due to him. If only the facts were discovered, it mattered not to him by whom the discovery was made; and windy battles over claims of priority or selfish struggles to pre-empt fields of investigation were alike impossible to him. The mere fact that his scientific contributions numbered fully eight hundred, conveys little idea of the range of subjects they covered; the epoch-making character many of them possessed; or the enormous amount of patient labor bestowed on the thousands of exquisite illustrations they contained.

<sup>1</sup> To be published in an early issue of the Journal.

<sup>1</sup> Printed in full on page 316 of the Journal.

Dr. Pepper congratulated the Association upon the interest taken in its meetings, and expressed great pleasure in the presence of the foreign guests.

#### REPORTS ON THE TREATMENT OF VISCERAL TUBERCULOSIS BY KOCH'S METHOD.

Report by DR. F. P. KINNICUTT, of New York. During the interval between December 10th and June 1st, forty-two patients suffering from various forms of tuberculous disease were inoculated with Koch's fluid, under Dr. Kinnicutt's personal supervision, in the wards of St. Luke's Hospital. Of these forty-two cases, but thirteen were of pulmonary tuberculosis. The results in these pulmonary cases were, that five were notably improved in both pulmonary and general condition, four showed no improvement or showed improvement in some respects but not in others, four showed distinct deterioration.

The impression which Dr. Kinnicutt received from an experience of nearly nine months in the treatment of various forms of tuberculosis with tuberculin, may be summarized as follows: Tuberculin possesses marked elective affinities for tuberculous tissues. Its value in deferential diagnosis is relative, rather than positive. Tuberculin not only does not produce immunity, but in certain cases apparently predisposes tissues contiguous to the seat of the original disease, as well as more distant structures, to infection. The fever and general constitutional disturbance produced by tuberculin are not only harmful, but are probably unessential to its remedial action. This clinical impression is strengthened by very recent chemical investigations, which indicate that tuberculin contains not one, but several, active principles, and that its activity in producing fever and constitutional disturbance is apparently dependent upon contained substances quite distinct from its remedial principles. Inoculations of minimum strength, gradually increased and given at longer intervals than was originally advised, constitute the safest and probably the most efficient method of its use.

As to the effects of tuberculin in the treatment of pulmonary tuberculosis; its remedial action is apparently restricted to pulmonary disease in its early stage. In such forms of tuberculosis, the most careful study of the individual, of the history and physical signs of the disease previous to inoculation, does not permit an opinion of the probable nature or degree of reactions or of the ultimate effect of treatment in any given case. The establishment of constitutional tolerance varies greatly in time in different individuals suffering from apparently similar lesions, and cannot be accepted as a basis for prognosis. Local reactions may continue to be developed under treatment, in the entire absence of constitutional effects, as indicated by the temperature curve. Tuberculin is apparently capable in exceptional cases, even of incipient disease, of exciting pneumonic processes (catarrhal and caseous hepatization) of varying degrees of intensity. Such processes are probably due to the conveyance into other parts of the lung of cheesy material and liberated bacilli. In cases of localized tuberculous pleurisy, the inflammatory action excited by tuberculin may lead to a general infection of the pleura. The production of hæmoptysis is comparatively rare. Its use necessitates the greatest watchfulness, and entails much anxiety on the part of the physician. The exceptional dangers and harmful action of tuberculin do

not preclude its employment, for it exercises a remedial action in a yet undetermined percentage of cases of pulmonary tuberculosis in its early stage, and an ameliorating effect upon many of the symptoms of more advanced disease. The complexity of the conditions often present, even in the early stage of the disease, and the idiosyncrasies of tissue reaction in different individuals, are suggested in explanation of the failure of a remedial action in cases apparently similar. The most recent observations give promise of an enlarged sphere of usefulness in modifications of the original preparation.

Report by DR. WM. OSLER, of Baltimore. In the medical wards of the Johns Hopkins Hospital inoculations were practised on twenty-eight patients. Twenty-two of these were cases of pulmonary tuberculosis, three were cases of pleurisy suspected to be tuberculous, two were for diagnostic purposes with negative results, and one case which was thought to be tuberculous adenitis proved to be cancerous. In giving the injections we began with small doses, and, as a rule, gradually increased if the patient had no reactions, in some instances going as high as thirty-five or forty milligrammes. Cases were selected which were, so far as physical examination could guide us, either in the early stage, or instances in which the disease was quiescent. The injections were not practised on any advanced case.

No case was cured. Five cases were decidedly benefited; the results being evident not so much in change in the physical signs as an improvement in the general condition and in weight: thus the cases which improved gained from nine to fourteen pounds. In not one did the bacilli entirely disappear from the expectoration. In all, the cough was reduced in frequency. Details of three of these patients could not be obtained; two of them were seen within a week. In one the improvement continues. Thus the second case on which it was used weighed on admission 114 pounds, and weighed on discharge 117½ pounds, and on the 13th of September weighed 126 pounds. In this case, too, there is an improvement in the physical signs, the râles having diminished in a marked manner. Another of the cases which had improved very much has lost ground through the summer, and on examination a few days ago the disease had evidently made progress. The five cases in which improvement was most marked were cases in which the disease was not very recent, having lasted from seven months to more than two years; but in all of them the trouble was more or less localized. Of the remaining seventeen cases, nine left the hospital distinctly rendered worse by the treatment. Of these, one died shortly after, and another a few weeks ago. Of the other seven nothing has been heard. In four the condition was not materially changed, and in four there was slight improvement, noted particularly, in the gain in weight.

No deaths occurred while the patients were directly under treatment. In one case not counted in this list, a patient had a single injection and in two days he developed signs of extensive pneumonia of the right base, which we were at first inclined to think might be a tuberculin pneumonia, but the persistent high fever and the progressive and rapid development of the consolidation, rather favored the view that it was an acute pneumonia. The autopsy made by Dr. Welch fully confirmed this. The bad results of the

treatment were evident in the increase in the consolidation, breaking down of the lung tissue, great increase in the fever, progressive weakness, and loss of weight. This was specially marked in several of the cases in which the disease was in an early stage. Of the three pleurisy cases, one gained 13½ pounds, a second 5½, and a third 10 pounds. These were instances of suspected tuberculous pleurisy, and there were reactions after the injections, but tubercle bacilli were not found in the expectoration.

On the whole we were, of course, disappointed with the results. We cannot reproach ourselves with a lack of care in the selection of the cases, as we exercised reasonable caution in choosing patients in a tolerably favorable condition, and in as early a stage as possible. The increase of dose which was carried out in many, but not in all, of the cases, may have been a mistake, but in this matter we followed, we believed, the best directions.

Report by DR. HAROLD C. ERNST, of Boston. My experience with tuberculin has apparently corresponded with that of most others. There is a marked and rapid improvement in certain cases, more especially those of external tuberculosis (including lupus), which goes on for a certain time and then stops, and the effect of the material is lost. The lesions even begin to retrograde. Seen at a certain time after the treatment has been going on, the results for the future are very apt to be gauged by what has been accomplished in the first of the treatment; and this is precisely what happened in my observations in Berlin. I saw there the same—only more marked—improvement in cases of lupus, pulmonary tuberculosis and surgical disease that has occasionally occurred here; but neither there nor here has the early promise been kept up.

My experience with tuberculin would lead me to take the following positions in regard to it:

(1) It has no diagnostic value that is at all applicable at present to clinical use.

(2) I have been entirely unable to demonstrate anything more than a possible temporary beneficial result (and this only in certain cases) in human beings, in any form of tuberculous disease.

(3) I have had no personal experience with its ill effects, but there can be no doubt that these occur.

(4) Its advantages, so far as I have seen them, would not induce me to use it again in practice.

There are, however, certain other points that should be well understood, before this material, or rather its source, should be given up for investigation. Some of these seem to me to be indicated as follows:

(1) Tuberculin itself is a very complex material, and its constituents must be separated and well-understood, before it can be definitely asserted that it does not contain something of value in compelling the healing process in tuberculous lesions; this is well shown by the results obtained by Hunter and Cheyne.

(2) The same thing is indicated even more strongly by the effects that seem to have shown themselves in the clinical experiments conducted with it; for while there has not been much actual healing to report, nevertheless, such effects have been demonstrated, that it is within the bounds of possibility to believe that by different methods of preparation a material may be obtained from pure cultures of the bacilli that may give more satisfactory results.

A preliminary paper on

# THE CLIMATE OF SOUTHERN CALIFORNIA FOR RESPIRATORY DISEASES,

by DR. NORMAN BRIDGE, of Los Angeles, was read by title.

J. WEST ROOSEVELT, of New York, read a paper on

# THE FREQUENCY OF THE LOCALIZATION OF PHTHISIS PULMONALIS IN THE UPPER LOBES.

It is well known that in a great majority of cases the earliest lesion of pulmonary phthisis is found in the apices of the lungs, and the writer reports certain work which he has done bearing upon the reasons for this localization.

The bacilli might be lodged by the air currents during inspiration in the places in which the tubercles are formed; or they might be first inhaled in the larger bronchi and there deposited during inspiration, and subsequently be forced into the upper lobes together with mucus, etc., during forced expiration, as in coughing, or during the normal quiet expiratory movement.

These explanations assume the existence of some mechanical disadvantages affecting the apical parts of the lungs, which cause either excessive inspiration power with relatively insufficient expiratory power, or possibly the later alone. It is often stated that the upper parts of the chest move less freely than the lower. This statement is, it seems to the writer, doubtful. Certainly in women the normal type of respiration is thoracic and the upper parts of the chest move freely, while in men the lower thorax and abdomen move most. If relative chest expansion determines the seat of the lesion, the marked difference between thoracic and abdominal breathing ought to affect its localization. It does not, however, for phthisis in the female has its earliest seat in the upper lobes, just as it does in the male.

It must be remembered that if the tubercle bacillus is actually lodged in the apices by respiratory movements, the same movements ought to produce the same result with the pneumococcus and with dust. Yet the pneumococcus in a large majority of cases is lodged in the lower lobes, and dust does not primarily and in any very marked degree affect the upper. Moreover, if, as has been suggested, during coughing the lower lobes pump their secretions into the upper, we should find the upper usually over-filled with such secretions at autopsies in cases of chronic or acute bronchitis, which is not the case.

The anatomical peculiarities of the pulmonary artery are such that it seems very probable that it is through this vessel that the bacilli pass and are thrown into the upper lobes, in the form of minute emboli, and that these are arrested at the places where the relatively large arteriole suddenly breaks up into capillaries in the lobules. The bacilli may enter the system through the systemic veins or the lymphatics. In the latter case they might be absorbed by any part of the lymphatic system, including the lymph vessels of the naso-pharynx, mouth, large bronchi and digestive tract, and enter the vena cava through the thoracic ducts. Having entered the right ventricle, they would be propelled with the blood through the pulmonary artery. In this vessel the momentum acquired by them would cause them to run along the upper walls of the main branches and to enter the branches which supply the apices.

In connection with the paper were presented illustrations of the anatomy of the pulmonary blood-vessels and of the bronchi, and also specimens showing the behavior of inhaled dust. There were also shown specimens of lungs which were so prepared as to maintain their normal elasticity. Demonstrations of the distribution of pigment in lungs, as shown in large, thick, transparent sections, were exhibited.

Dr. W. H. WELCH, of Baltimore, expressed his appreciation of the experimental and anatomical work relating to the lungs which has been performed by Dr. Roosevelt. The most important part of the paper, he thought, was that which gave the experimental proof that small particles, when inhaled, go only a comparatively short distance into the bronchi, and that the mechanical and other conditions usually assigned for the assumed frequency of penetration of tubercle bacilli along the air-passages into the apices of the lung are either not operative or do not exist at all. He not only criticised acutely the current theories on this subject, but has brought direct experimental evidence against them; and this is to be welcomed as a genuine and important contribution to our knowledge. Dr. Roosevelt's suggestion that we may perhaps better explain the common localization of tuberculosis at the apex, by assuming that the bacilli are conveyed there by the blood-current rather than by the air-passages, is open to serious objections. He has himself pointed out the manifest difficulties which this hypothesis meets in the known behavior of emboli carried to the lungs by the blood circulation. It matters not whether these emboli be large or small, heavy or light, portions of thrombi or tubercle bacilli detached from a tuberculous thrombus in the thoracic duct, there is evidence from post-mortem observations on human beings that they have no preference for lodgement in the apices of the lungs. Again, in order to explain the more frequent occurrence of pulmonary tuberculosis at the apex, is it necessary to demonstrate that tubercle bacilli are more frequently carried there than to any other part of the lung? May we not equally well assume that even if the bacilli are conveyed no more frequently, or possibly less frequently, to the apex, that they find there specially favorable conditions for their invasion and growth; whereas, under ordinary circumstances, they do not find similar conditions when they enter other parts of the lungs?

Dr. WILLIAM M. ORD, of London, endorsed Dr. Welch's criticisms. He has long thought that the localization of tuberculosis at the apex of the lung is chiefly determined by a selective power existing in that part of the lung which offers increased facility for the deposit or further development of the bacillus. The apices of the lung are much more prone to smaller localized inflammations, to that kind of process in which we know that the tubercular bacilli readily find a nidus for their development. Studies in comparative anatomy seem to show that the apical portions of the lung are not as highly organized as the basical.

Dr. JACON, of New York, expressed the opinion that in all probability those cases of tuberculosis which are the result of embolism (unless they are miliary) are rare compared with those that are the direct result of the location of the bacillus on and in the mucous membrane. That, just as in diphtheria, in order to have an invasion you must have a diseased mucous membrane, you must have an abnormal condition of the epithelium. In most cases of extensive

tuberculosis in the young, cavities are found at least just as many times, and probably in the great majority of cases, in the lower lobes. The reason for this is probably because the epithelium in these portions of the lungs was broken down in consequence of the lobular pneumonias and catarrhs, which take place more frequently in the lower lobes. Is it not true or probable that there is an abnormal condition of the epithelium in the apices of the lungs of the adult similar to what is so frequently found in the lower lobes in the very young?

Dr. V. C. VAUGHN, of Ann Arbor, agreed with Dr. Roosevelt's criticisms of other theories, but could not accept Dr. Roosevelt's own theory. It is exactly those cases which result from inoculation through the blood and lymph which are not localized in the apices. Experimentally introducing tuberculosis by way of the intestinal canal, the tuberculosis develops in the mesentery and in the intestines, or, if in the lungs, not specially localized in the apices. Clinically, tubercular disease of children is mostly of the intestines and mesentery, and when in the lungs, is not especially localized in the apices. When we inject cultures of the bacillus tuberculosis into the blood, we do not get special localization in the apices.

Dr. ROOSEVELT: The work of destruction is, of course, easier than that of construction, yet it is worth while to attack all theories, for if they are demolished they must be false and misleading. This theory was not advanced as proven, but it seems plausible in spite of the perfectly just objections advanced by Dr. Welch. The conditions referred to in the paper do not resemble those which obtain when an enormous number of bacilli are continually being poured into the blood from a tuberculous thoracic duct, or when a blood-clot large enough to occlude a large branch of the pulmonary artery is concerned.

The question of local vulnerability as determining a soil suitable for bacillary growth was not considered, because it is something so vague and intangible that I desired, if possible, to ascertain whether some physical explanation could not be discovered which would be more comprehensible.

The most important point in the paper is to establish the fact that inhalation does not account for the phenomenon. This is a matter of practical value, for it makes it the more important to appreciate the risk of tubercular infection in other ways than through the air.

(To be continued.)

## Recent Literature.

*On Painful Menstruation, the Harveian Lectures, 1890.*

By FRANCIS HENRY CHAMPNEYS, M.A., M.D. Oxon., F.R.C.P. London: H. K. Lewis. 1891.

The main interest in these lectures lies in the pathological interpretation which the author gives to the question of dysmenorrhœa. Briefly stated, his views are these: He narrows the variety of dysmenorrhœa to two, inflammatory and spasmodic, and the first he does not consider, strictly speaking, dysmenorrhœa, "for the pain in the majority of cases principally occupies the inter-menstrual period, and is relieved by the flow." That leaves only the spasmodic, to the most remarkable subdivision of which, membranous

dysmenorrhœa, he devotes the whole of the second lecture. He very thoroughly reviews the literature of the subject, and in discussing the cause of the pain, concludes that it is due to colic excited by the passage of a foreign body over a specially sensitive part.

In the third lecture he discusses spasmodic dysmenorrhœa. The mechanical obstructive theory is very sharply criticised, and in our opinion effectually controverted. His views are that spasmodic dysmenorrhœa is pre-eminently an affection of the immature uterus, that the pain is certainly colic, and that it is essentially a neurosis.

His views as to treatment we agree with, and we consider the book as on the whole a very thorough and important contribution to our knowledge of this subject. This short *résumé* has not done justice to the amount of work which is represented. There is incidentally a very interesting discussion of the phenomena of menstruation, especially of the changes which occur in the mucous membrane. It is a book which will well repay reading.

*Manual of the Domestic Hygiene of the Child; for the use of Students, Physicians, Sanitary Officials, Teachers and Mothers.* By JULIUS UFFELMANN, M.D., Professor of Internal Medicine at the University of Rostock. Translated, with the author's kind permission, by HARRIOT RANSON MILLINOWSKI, edited by MARY PUTNAM JACOBI, M.D. New York and London: G. P. Putnam's Sons. The Knickerbocker Press. 1891.

This treatise of some two hundred and twenty-five pages contains much valuable information for both the laity and physicians. It is more than ordinarily attractive in its type and in the size of its pages.

We do not, however, agree with the editor that a book like this can, as a whole, be made safe reading for American mothers. Parts of the work such as the chapters relating to "The Care of the Nervous System," and "The Intellectual Health of the Child," may well be appreciated by the average mother. Much of the earlier part of the book, however, contains statements, which not only the average mother would find difficult to understand, but many of these statements would indeed be questioned by physicians familiar with the advance which has of late years been made in infant feeding. The book in parts strikes the reader as being a little behind the times and as having been written some years before it was published. The discussion of proper methods of preparing an infant's food depends for its value on a correct basis of chemical analysis from which to start, and it is therefore unfortunate, to say the least, that the old analysis of Vernois and Becquerel should be introduced as authoritative. Professor Uffelmann does not seem to have a complete grasp of the subject of infant feeding as studied in the light of the latest investigations which have been made in America. Under these circumstances it seems to us that the translator is decidedly reversing the proper source from which "grateful acknowledgment" should come, when in her introduction she says, "The author has freely availed himself of American reports and statistics, with a liberality so rarely shown by European writers that it calls for grateful acknowledgment." Why the giver should be grateful to the receiver it is difficult to see, but perhaps we are wrong in doubting whether the best on all medical subjects must necessarily emanate from European sources.

## IS IT POSSIBLE FOR CRIMES TO BE COMMITTED UNDER HYPNOTIC INFLUENCE?

THE question whether there is a likelihood that crimes will now and then be committed under hypnotic influence, has been answered differently by different authorities; some, as Charcot and the Salpêtrière School, maintaining that little danger is to be apprehended from this source, others, as Brouardel and Bernheim, answering the question in the affirmative.

The sentence not long ago of a hypnotizer to penal servitude, for procuring from a somnambulant a check for 10,000 francs, brings home to us, says the *New York Times*, as a practical matter, the possibilities for crime which the facts of hypnotism offer.

*Per contra*, in a famous murder case tried in Paris last year (the Eyrard-Bompard trial<sup>1</sup>) in which one of the defendants claimed irresponsibility on account of being under hypnotic influence, the jury did not allow the plea.

In a recent work "On Hypnotism and the Analogous States, from a Medico-Legal Point of View," Gilles-de-la-Tourette traces the history and development of hypnotism from the days of Mesmer, the charlatan, to the recent date when Charcot undertook the study, in 1878, as a purely scientific question. He is of opinion that as aids to crime by suggestion the abnormal states comprehended under that term are of extremely little account in real life, however startling some of the effects may be in the experimental laboratory. Rape is, according to this writer, the only crime which has thus far been accomplished with the aid of hypnotism under the form of lethargy.<sup>2</sup>

On the other hand, Brouardel's report to the French government presents striking facts to substantiate the view that hypnotism, in the hands of unscrupulous performers, may be made a powerful instrument of crime. Perfectly conscientious persons, under the influence of hypnotic suggestion, were made to take the initiative in deeds of revolting criminality.

<sup>1</sup> See page 73 of the Journal of January 15, 1891, quoted from Sajous's Annual.

In a lecture lately given in the amphitheatre of the Salpêtrière,<sup>3</sup> Dr. Auguste Voisin discusses what he calls "a crime of arson committed by a person while in the hypnotic sleep." His illustrations belong rather to the department of laboratory experiments than to real life. Should such a crime be committed, he says, there is a sure way of detecting the true culprit. Hypnotize the individual who has committed the criminal act; interrogate him while in this second state, "and his conscience, now become free, will compel him to tell the truth and criminate the man who instigated the deed." It was in this way, Voisin says, that he brought out the truth in regard to a female who had been sentenced to Saint Lazare for larceny, obtaining the discharge of the prisoner by proving that for several months she had been under hypnotic influence while committing repeated thefts which had been "suggested" to her in this irresponsible state.

Any discussion of this subject would be incomplete that did not allude to Kingsbury's article in a late number of the *Nineteenth Century*, also Croft's article in the *North American Review* for August, 1888.

Kingsbury's paper is entitled "Hypnotism, Crime and the Doctors." He begins by contradicting the assertion almost universally believed in, that hypnotism can make the subject believe, feel, or do anything that is suggested to him, regardless of his moral convictions or even his natural instincts. This he asserts to be absolutely erroneous, only about fifteen per cent. among patients being susceptible to the influence. He bases his figures on his own practice and on the experience of Continental physicians. He states that while this percentage may pass into a condition of somnambulism, only a very small number can be reduced to that state of utter irresponsibility which is popularly supposed to be the state of every hypnotized person.

Kingsbury demands that ignorant dabblers in hypnotism be restrained by law from trying experiments; that public exhibitions of hypnotism, being generally made with subjects hired for the occasion and adapted to the production of sensational effects, be prohibited; that all employment of hypnotism, although he would not confine it to medical practitioners exclusively, should be restricted in the same way as vivisection, to men who devote themselves to it scientifically, and should be practised by license only.

Croft's article is entitled, "The Open Gate of Dream Land." He professes to write from large experience. He devotes considerable space to the question whether crime can be committed by the aid of hypnotism. He thinks that instances must be very few where the mesmerized subject can be so dominated by the hypnotizer as to lose the natural moral sentiment. To quote his words: "A young lady, one of the brightest sensitives I have ever seen, steadfastly refuses to play cards. I tell her she is Buffalo Bill, and easily induce her to assume his character, but when card are suggested, 'No I never play cards. It

is wrong!' she says, and I cannot move her. I could make her jump out through the window, or put her hand in the fire, but play cards she will not. I was puzzled by it, till on inquiring I ascertained that her religious parents had brought her up very strictly, and taught her that it was wicked to play cards."

Other instances of a similar kind are adduced. "The conduct of hypnotized subjects," he says, "cannot be positively predicted. The mental impression may not in a given case be sufficiently vivid and dominating to induce action, or the intention may be counteracted by the trained moral sense asserting itself and overbalancing the confused hypnotic tendency."

As for the ability of the hypnotized person to accomplish at a distance and while in the somnambulist state acts suggested by the hypnotist, this writer speaks very doubtfully. "A mesmerized person sees nothing but his ideal realm, the world of transient hallucinations in which he dwells. He is in a state of somnambulist coma, and his fancies are insane delusions, bearing no relations to the actual things around. Mesmerized sensitives are bewildered and helpless when away from the mesmerizer, and I have seldom seen one who was sufficiently self-controlled to go even a hundred feet away from me and do anything he was told to do." This has been the experience of other experts, as Lollingwolf, who has sent out hypnotized subjects to execute some command, and has known them to wander blunderingly about the yards of private houses, thinking they were in the street, or fall down in the street in a state of lethargy. It would seem from this last writer's statements that such abolition of the moral instincts as would make the mesmeric subject (or "responsive," to use the technical language of certain of these authorities) a ready perpetrator of criminal acts can only accompany a profound somnambulist condition in which the individual is unconscious of his surroundings; he would, in fact, have a very low opinion of the moral status of any person who, however much in rapport with the hypnotist, could be influenced by suggestions to crime while in the waking state.

From what has been said, it will be seen that the hypnotic influence may, in some instances, be abused to the detriment of others by unscrupulous persons, though the danger from this source is easily exaggerated; the conclusion, at any rate, is legitimate, that hypnotism is a power which should be exercised cautiously, conscientiously, and under restrictions and conditions which should be clearly defined.

#### INDEX CATALOGUE OF THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE. VOLUME TWELVE.

"Of late years those physicians in this country who make use of medical literature in connection with their investigations or writings, have, for the most part, become acquainted with the resources of the Library of the Surgeon-General's Office, as it is offi-

<sup>3</sup> *Lectures on Ther.*, Aug. 30, 1891.

cially designated, and many of them are much interested in its progress and prospects."<sup>1</sup>

Such is the opening sentence of an article on "The Condition and Prospects of the Library of the Surgeon-General's Office and its Index Catalogue," by its librarian.

If an additional stimulus to the general interest in our national medical library were needed, it could be found in the new volume of its "Index Catalogue," which carries the index to *Shuttleworth*, and adds to it 20,251 author titles, representing 8,022 volumes and 18,090 pamphlets. It also includes 6,603 subject-titles of separate books and pamphlets, and 18,956 titles of articles in periodicals.

The first twelve pages of the present volume are taken up with the "Fifth Addition to the Alphabetical list of Abbreviations of Titles of Medical Periodicals employed in the Index Catalogue, published in the Seventh Volume." These additions have been published annually for the last five years, and the present number represents one hundred and seventy-six hitherto unmentioned periodicals received by the library, which with few exceptions, are new periodicals which have sprung into existence within the year. Many of them are annuals, and reports of Congresses; but counting only such periodicals as from their titles may be called medical journals, and which are published at least as often as once in three months, there appear to be twenty medical journals which have sprung into existence in the United States during the past year, besides four journals which have either changed their titles or resumed publication after a temporary suspension. This is too large a number to represent actual additions to medical literature, but if the new journals are to be regarded as medical newspapers, they may be considered as representing an actual educational advance.

Veterinary surgery and comparative pathology are assuming an important place in the library, if we may judge by the additional veterinary journals, and the titles to be found in the text under the heads of "Sheep," "Sheep Pox," "Rumination," and "Ruminants."

It is not worth while to enumerate the different subjects indexed in this volume, but it is of interest to note that the present series of the Catalogue will be finished, if expectations are realized, in three years, when subjects will have accumulated sufficient for an additional five volumes.

#### MEDICAL NOTES.

**RUSH MEDICAL COLLEGE.**—At the opening of the session of the Rush Medical College in Chicago, on September 29th, a bronze bust of the late Dr. C. T. Parkes was unveiled, with appropriate ceremonies.

**THE INTERCONTINENTAL AMERICAN MEDICAL CONGRESS.**—The Committee on Permanent Organization of the Intercontinental American Medical Con-

gress will meet at the Lindell Hotel, St. Louis, on October 14th. It is intended at this meeting to (1) adopt a constitution; (2) elect permanent officers, domestic and foreign; (3) select the time and place of meeting. Members of the auxiliary committees of the different States are invited to be present.

**GACETA MEDICA QUEZALTECA.**—Under this title the first number of the first medical journal published in Guatemala appeared on September 1st. It is to be published in Quetzaltenango on the 1st and 15th of each month.

**THE AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION,** which was organized last February in New York, held its first annual meeting in Philadelphia, September 24th to 26th, under the presidency of Dr. E. Betton Massey. A large number of papers were presented.

**CHANGES IN FOREIGN UNIVERSITIES.**—Dr. Carl Maydl, extraordinary professor of surgery in the University of Vienna, has been appointed ordinary professor of the same subject in the Czech Medical Faculty of the University of Prague. Professor du Bois-Reymond has been elected Dean of the Medical Faculty in Berlin. Professor Gartner, of Jena, has been appointed to the chair of hygiene at Marburg, vacant by Professor Rubner's appointment to succeed Koch in Berlin. Mosetig-Moorhof has been given charge of the second surgical department of the Vienna General Hospital, formerly under the charge of Salzer, deceased.

**REGULATIONS REGARDING POISONOUS DRUGS.**—The German Bundesrath has issued a series of regulations bearing on the sale of poisonous drugs. A long list of drugs is printed which are only to be sold in retail on the prescription of a medical man, a dentist, or a veterinary surgeon, and a fresh prescription, properly signed and dated, is to be required for every fresh supply furnished. All fluid medicines for internal use are to be dispensed in rounded vials, and the label is to be of a white ground, whilst medicaments for external use are to be dispensed in hexagonal bottles with three of their surfaces plain and three fluted, whilst the ground color of the labels is to be red. These regulations do not come at once into force, however, and as they are permissive, each State will enforce them or not as they think best.

**FAMINE IN RUSSIA.**—A despatch from St. Petersburg announces that in addition to the scarcity of food which has caused untold suffering, the distress has been intensified by the enormous number of unusually disastrous fires that have occurred throughout the famine-stricken districts. In many of the districts entire villages have been destroyed. What little food it is possible for the peasants to obtain is of the vilest description. In many cases their only food is the sweepings and refuse from the flour mills. In Saratoff the land-owners found this refuse so injurious to their cattle they would not feed it to them. But, though it was not fit for cattle to eat, the land-owners

<sup>1</sup> Journal, page 341.

made bread of it, and sold it to the peasants. Bread made of finely chopped straw and bran mixed with a very small quantity of rye, is considered a godsend. In many districts the starving peasantry are not able to procure even these miserable substitutes for nourishing food, and are reduced to dire straits to procure anything that will prolong life. A circular has been issued by the Minister of the Interior, which enumerates thirteen governments in which the people are completely famine-stricken, and eight in which a partial famine prevails.

**TRICHINOSIS ON BOARD SHIP.**—The German medical journals, as well as the daily press, have recently been saying harsh things about the American hog, basing their remarks on the report of the outbreak of trichinosis on board the Bremen barque *Nice* at Iquique, owing, as was at first believed, to the crew having eaten pickled pork of North American origin. The occurrence was pointed to as fully justifying the exclusion of American pork and bacon from Germany. It turns out, however, that the incupated pork was undoubtedly Chilean, and was purchased in the market at Iquique; furthermore, it was not pickled at all, but fresh, and it appears to have been eaten raw by the crew. Of the seventeen men who partook of the stuff, all suffered from trichinosis. The incident would seem to point the moral, not so much that American pork is unsafe to eat, as that the habit of eating pig's flesh uncooked is dangerous as well as disgusting.

#### BOSTON AND NEW ENGLAND.

**HARVARD MEDICAL SCHOOL.**—The number of new matriculants this year thus far is 156.

**MEDICAL ATTENDANCE IN THE JURY-ROOM.**—The sanctity of a jury-room appears to be so well guarded, that even in case of sudden sickness, a physician may not enter except after due process of law. In the Foss Will case, tried recently in Boston, the jury were deliberating, when, late in the evening, one of them was suddenly attacked, with what proved to be a stroke of apoplexy. The officer in charge notified the deputy-sheriff, who, not having authority to let any one into the jury-room, drove across the city and informed the sheriff, but even this official was not high enough to act, and another expedition started in search of the judge. As the latter happened to be at home, the requisite order was obtained to summon a doctor.

**CITY HOSPITAL IN MALDEN.**—The corner-stone of a new city hospital was laid in Malden, Mass., last week.

**DIPHTHERIA IN MELROSE.**—A large number of cases of diphtheria have recently occurred in Melrose, Mass. It is reported that an investigation has disclosed the fact that the disease can be traced to the milk-supply.

#### NEW YORK.

**THE DEATH-RATE.**—During the week ending September 26th, there were reported 811 deaths, an increase of 83 over the number reported in the week

previous. This increase was no doubt due in great measure to the unusually warm weather that prevailed, and of the 116 cases of deaths from diarrhoeal diseases reported, 104 were in children under five years of age. There were 24 deaths from typhoid fever, as against 19 the week previous.

**POLICE MATRONS.**—At last the cause of decency and humanity in the matter of police matrons, has triumphed in New York. Three were appointed on September 29th, and thirteen more are to be selected as soon as provision can be made for them at the station-houses.

**SMALL-POX AND QUARANTINE.**—When the steamer *Waesland*, from Antwerp, reached quarantine on September 9th, her captain reported that during the voyage a steerage passenger had died of small-pox and been buried at sea. Health Officer Smith at once had the vessel fumigated, and transferred the 800 steerage passengers on board to Hoffman Island, where they were vaccinated and detained under supervision until September 23d. During this time one case of small-pox developed, and the patient was at once taken to the hospital on North Brothers Island. It was then deemed safe to allow the rest of the passengers to come to the city; but, unfortunately, it proved a little too soon. Since then no less than eleven cases have been detected among these immigrants, and it is possible that others may have developed among those who have already started for the West. This has put the officials of the Bureau of Contagious Diseases on the alert, and every precaution has been taken to prevent a further spread of the disease. Since the discovery of these cases the Bureau has vaccinated over two hundred and fifty persons living in or near the premises where the patients were found.

**AN EPIDEMIC OF DIPHTHERIA**, the origin of which has apparently not yet been determined, prevails at Coegman's, on the Hudson, and Dr. J. G. Mosher, the local health officer, has ordered the public school closed. One of the teachers is reported at the point of death. All social entertainments have been abandoned, and some families with small children have left the village to remain until the danger is past.

#### Miscellany.

#### AN EXPERIMENT IN HUMAN STIRPICULTURE.

At the meeting of the American Association for the Advancement of Science, held in Washington in August, a paper was read by Mrs. A. N. McGee, describing an extensive and systematic experiment in human stirpiculture, carried on during the years 1868 to 1879 in Central New York. The originator of the experiment was a zealous but logical enthusiast, the late John Humphrey Noyes; the purpose was the promotion of sanctity; the place and the means were the Oneida Community. In early life Noyes founded the peculiar sect called perfectionists, which in 1848 gathered disciples to the number of eighty-seven at

Oneida. Here the community of goods and also of persons were practised.

Until 1868 the birth-rate in the community was carefully limited, but at this date, financial success being assured and the members having increased to 250, the experiment in stirpiculture was begun. Its object was the increase of sanctity in succeeding generations, in order that sin, disease and finally death might be abolished. Physique, intellect, hereditary qualities, mutual attraction, etc., were secondarily considered.

The first principle of this stirpiculture was continued in-and-in breeding with a judicious mixture of foreign blood from time to time. Its second principle was the careful selection of individuals. From 1869 to 1880 many children were born in pursuit of this plan. Of these five died at birth from unforeseen causes and one child was acknowledged a failure physically. Otherwise the experiment was progressing admirably, the children were given the best of care, when an unexpected result caused the failure of all Noyes's plans. The spirit of monogamy, ruthlessly kept in check before, became so strong in consequence of the mating of one-quarter of the community for stirpicultural purposes that the complex marriage system was given up in 1879. The dissolution of the Oneida Community by mutual consent followed a year later.

Of the stirpicultural children only one has since died. The others, now aged from eleven to twenty-two years, are, on the whole, somewhat above the outside average in physique and intellect. The blood of the children came largely from farmers and mechanics, with a strong infusion from the intellectual Noyes family. It is therefore noteworthy that of the oldest sixteen boys ten are in business as clerks, foremen, etc.; one is a musician of repute, two are students of law and medicine, two at college and only one following a manual occupation, being a mechanic. Of the oldest six girls, two are at college and one is a student of the kindergarten system.

In conclusion, Mrs. McGee said that the main object of the experiment has not yet been attained. Only one of the children is a perfectionist, and he was born of an uncle and niece. Of the rest, but few are regular church members. This experiment would therefore seem to show that while the race could doubtless be improved by more attention to stirpiculture, yet when directed to the perpetuation of a belief, success cannot confidently be expected.

#### SHORTENING OF BIEDERT'S METHOD FOR FINDING TUBERCULAR BACILLI IN THE SPUTUM.

DR. KRONIG<sup>1</sup> has applied the centrifuge to the examination of the sputum, with the result that a considerable number of tubercular bacilli were found in a case where the ordinary method had failed to reveal them. The sputum was diluted with a solution of caustic soda, and on the application of centrifugal force for five minutes, a somewhat compact sediment was separated, which gave the above result on examination. By Biedert's method the sputum so diluted has to stand for two or three days to allow of the precipitation of the bacilli. Professor Litten has explained the application of Steubeck's centrifuge to purposes of clinical medicine.<sup>2</sup>

<sup>1</sup> Berlin, klin. Woch., July 20.

<sup>2</sup> See page 121 of the Journal.

#### TWO RECENT CONTRIBUTIONS TO THE SUBJECT OF PRE-HISTORIC SYPHILIS.<sup>1</sup>

IN an exhaustive discussion of the question of the existence of syphilis among the inhabitants of America before the discovery by Columbus, Hyde,<sup>2</sup> after an elaborate historical review, revealing an epidemic in Spain, just about the time of Columbus's sailing, describes many instances of the discovery of bones bearing what has been supposed to be unmistakable evidence of syphilitic lesions. One element, however, he says, he has been wholly unable to establish beyond a peradventure, namely, that the bones, which he has examined either directly or from photographs, were genuinely pre-historic; and, moreover, he does not think that any means exist of proving that the lesions found on the bones were produced by syphilis and nothing else but syphilis. Dr. Hyde says that until we are able to prove beyond a doubt that the burial places of these bones have never been interfered with since pre-Columbian times, we cannot be absolutely sure that syphilis existed among the Indians of those early days.

Contemporaneous with this article in this country, Proksch,<sup>3</sup> writes about the probable existence of syphilis among the old Egyptians. In studying a papyrus containing instructions for the management of different manifestations of a disease known to the old Egyptians as *uxedu* (so spelt in the original article), Proksch traces out syphilis. The papyrus gives the treatment for *uxedu* in the anus, in suppurating wounds, in the mouth, in the eyes, in the bones, in tumors of the head, in the body, in pustules, etc., herein giving an almost complete history of the various situations in which syphilis may manifest itself. The author concludes that *uxedu* of the old Egyptians is our syphilis.

#### TETANUS NEONATORUM OF ST. KILDA.<sup>4</sup>

ST. KILDA is a small island of the Hebrides group on the West coast of Scotland. It lies far out at sea, and the population consists of but eighteen families. From time to time the prevalence of tetanus neonatorum on the island has been noticed. A description of the disease has recently been published by a nurse who has spent a year on the island. Not more than one out of every four or five children born survives, the vast majority succumbing to this terrible malady. The trismus generally appears at about the fifth or sixth day, and coincides in its commencement with the separation of the umbilical cord. At birth the children look plump and healthy, and, so far as can be seen, no abnormality is present at the umbilicus either before or after separation of the cord. The illness begins with a low, whining cry, and usually terminates in death within twenty-four hours. The child is seized with a series of opisthotonic convulsions, in which the fists are clinched, the jaws tightly closed, and the spine curved. The fits recur every quarter of an hour until death from exhaustion takes place.

The natives are not robust. They live in small, dirty, ill-ventilated houses, with every condition favorable to the development of the disease.

## RUPTURE OF THE STOMACH.

DR. KEY-ABERG publishes in a Scandinavian medical journal an account of a case in which the stomach of a patient seemed to have been ruptured from the use of a stomach-pump.<sup>1</sup> The patient was a man who had taken fifteen grains of opium with the object of committing suicide, and who had not been brought to the hospital until three hours had elapsed. Under these circumstances the stomach was washed out somewhat hastily several times; each time it was remarked that only a portion of the water that had been injected returned. The patient died three hours after admission. At the necropsy it was found that the small curvature of the stomach had sustained several longitudinal ruptures, which, however, were confined to the mucous coat. The author was induced by this observation to make some experiments on dead bodies, which showed that an injection of three or four quarts of water into the stomach under a pressure of about ten inches of water produced similar injuries, and that these gradually increased, and ultimately became complete ruptures through the whole of the coats of the organ.

## THE INFLUENCE OF BITTER AND AROMATIC SUBSTANCES ON GASTRIC SECRETION AND ON DIGESTION.

THE action of bitter and aromatic substances on gastric digestion has been a subject of much controversy, although their use in therapeutics has been long established.<sup>2</sup> Some believe that bitters stimulate the stomach to greater secretion of mucus, and interfere with the digestion of albuminoids; these consider that any increase in the secretion of gastric juice resulting from their use is a pure supposition. Others, again, consider that bitters excite the function not only of the gastric glands, but also of the muscular walls of the stomach. Professor G. Marcone (*Riforma Medica*, June 8, 1891) has endeavored to settle the question on a sound physiological basis. He has studied the action of sixteen drugs belonging to the various groups of bitters, aromatics, and stimulants, and finds that all, without exception, cause increase of the secretion of gastric juice. Mixing the drug with food, prepared always in the same manner: the period of digestion is shortened; the quantity of gastric juice is increased; the movements of the stomach are more active and more efficient, and the gastric juice, increased in amount, retains its full digestive power. Introducing the drug into the empty stomach: the quantity of gastric juice is increased, and the juice retains undoubted digestive power. These results were verified by control observations made with distilled water in place of drugs. In order to ascertain, if possible, whether the action above observed was of local or reflex origin, the vagi were divided in the neck previous to the introduction of the bitter substances. Under these circumstances the contents of the stomach did not increase, and, notwithstanding an increase of acidity, the digestive power of the juice was much diminished. Marcone therefore concludes that the greater part of the effect of bitters is due to stimulation of the vagus endings in the stomach, whence by a reflex action both the secretion and the peristalsis are increased.

<sup>2</sup> *British Medical Journal*, July 4th.

## THERAPEUTIC NOTES.

BRANDY WITH EGG. — To administer brandy to infants, Eloy<sup>1</sup> recommends the following:

R Brandy . . . . .	3 i.
Cherry-laurel water . . . . .	gitt. v.
Yolk of egg . . . . .	No. ij.
Powdered sugar . . . . .	3 vi. M.

To be given in the course of a day, a small spoonful at a time.

EUPHORINE.<sup>2</sup> — Euphorine, or phenylurethan, which was discovered by Sansoni, is a white crystalline powder with a slight aromatic smell, and readily soluble in wine, which forms a convenient medium for its administration. Sansoni prescribed it in cases where antipyretic, antiseptic, antirheumatic, or analgesic action was required, and stated that it was free from any objectionable action, such as occasionally follows antipyrin, antifebrin, phenacetin, salicylate of soda, and other drugs of a similar class. A number of recent observations have been made, especially on rheumatic cases, in Professor Süller's wards in the Jewish hospital in Pesth. In three cases of supra-orbital neuralgia, and in three cases of sciatica, a cure was rapidly effected, a case of chronic nervous headache was decidedly improved, two cases of rheumatic fever were cured, but in another which was complicated with endocarditis no improvement was obtained, though here salicylate of soda was more successful; in nine cases of chronic articular rheumatism good results of a more or less permanent character were obtained; in three cases of muscular rheumatism a rapid cure resulted; and, lastly, in six cases of habitual hemicrania seen in private practice, the remedy produced an almost magical effect. The doses employed were from three to six grains, and were repeated from three to five times a day.

THE IODIDES IN SCROFULOUS CHILDREN.<sup>3</sup> — Iodine and iodoform give better results than the alkaline iodides. To young children tincture of iodine may be given, one drop daily in a little thin porridge made of farina and milk. Besnier<sup>4</sup> prefers the use of iodoform, which may be given continuously for a long time. He prescribes it after the following formula:

R Iodoform . . . . .	gr. iss.
Meliss . . . . .	3 iv. M.

KEROSENE AS A DISINFECTANT FOR INSTRUMENTS. — Lavrentieff<sup>5</sup> finds that by keeping surgical instruments immersed in kerosene perfect asepsis is secured, and that the instruments do not become corroded.

## Correspondence.

## ROME AND HER HOSPITALS.

Rome, August, 1891.

MR. EDITOR: — The time is not far off when the next International Congress meets, and as the "City of the Seven Hills" has been selected as the place for this important assembly, it may be of some interest for those who may contemplate making the journey but who are unacquainted with the climate and surroundings of this ancient and yet famous city, to learn something regarding them.

To begin with, an impression commonly prevails that the

<sup>1</sup> *Rev. de Clin. et de Ther.*

<sup>2</sup> *Lancet*, July 1.

<sup>3</sup> *Ann. Jour. de Med. Sci.*, September.

<sup>4</sup> *Le Bulletin Médical*, 1890, p. 595.

<sup>5</sup> *Saratovsky Sanitarny Obozr.*, No. 9, 1891.

summer season in Rome is unhealthy, that the atmosphere is malarial, and that the heat is unbearable; besides, that it is an old, antiquated centre, out of the range of ordinary travel, and of little interest to any one, other than the theologian and historian. These, however, are all positive fallacies. The sanitary condition of the city is not only excellent, but I believe is unrivalled in every other city in Europe or America.

In its water-supply Rome leads the world,—with its thousands of fountains in every conceivable form and situation through which issue jets and streams of pure, limpid water, so cool at all times that no ice is needed to reduce its temperature. Indeed, a small ocean must be delivered from the Apennines, through the ancient and modern aqueducts, which lie deeply buried, and course under the earth's surface in every direction.

The early founders of Rome, too, were well versed in physics, in hydrostatics; for its system of drainage and sewerage seem to be ideal.

I am credibly informed, that there has been no malaria of a severe type in Rome for many years, but that, in its out-lying, adjacent districts, there are yet seasons when its most serious manifestations are encountered.

The dwellings, churches, and public buildings are all well ventilated. And one will scarcely walk a hundred yards in any one direction without coming into an open space—a piazza. Many of these are sheltered by the leafy olive and are delightfully cool and quiet places, where, while resting the body, one can occupy his mind in the contemplation of what Rome, in past centuries, has accomplished in the arts and sciences. That the early founders of this city were hygienists of the first order, centuries of time have inevitably demonstrated.

Rome is not behind in hotels, either in quality or number. The accommodations are excellent and the rates moderate, generally less than in Paris or London. For vehicles, there is an abundance of victorias and of one- or two-horse street-cars and busses, running early and late, with the rate for travel, in all, about half the American.

In a general way, one can conceive of no city in the world of greater interest to physicians.

With regard to the weather, I must say that there is no such oppressive heat here, as we have in New York, in all our southern cities, and, in the greater part of those in New England.

The city is clean, orderly, and well policed.

Until quite recently, it is said, Rome was not well provided with hospital accommodations; but since "75" several monasteries have been appropriated by the medical brethren, and utilized as hospitals. They are not all that one could desire, yet, they are large, commodious and well lighted.

St. James's Hospital (on the Via Corsa) is the principal surgical hospital. There is a large and active service here. In one ward I saw twelve women who had been laparotomized in one month. In this hospital their results are marvellous, as I was informed by Professor Leoni and Dr. Bastianelli, that in their last two hundred cases of laparotomy they had but one per cent. mortality.

The Consolation Hospital (*Ospedale Consolazione, Piazza del Forum*), is the principal hospital in the city for traumatic surgery. Here, Professor Postempski has, within a month, performed his fourteenth abdominal section for penetrating wounds of the peritoneum, all inflicted with a blade, mostly the stiletto. Every one of his patients recovered.

The Hospital of the Lateran (*Ospedale del Laterano*), contains four hundred females, forty beds being exclusively employed for gynecological cases. This is a very fine building with two, long, airy, high stretches of the walls of Cæsar's time coming to an angle and enclosing the yards.

There is one institution here for consumptives, almost exclusively. It contains nearly three hundred patients, and was well known for being the principal Italian hospital in which Koch's lymph was tried. It has been wholly rejected.

Chloroform is the only anæsthetic employed. In fact, from the specimens of sulphuric ether which I saw in different places, it would seem that they do not know how to make the pure article in Europe. Many surgeons have informed me that this is why they do not more often employ it. Antiseptic solution they employ on the surface, never in the serous cavities, unless in the presence of decomposing matter. As in most of the Vienna clinics, they use nothing but silk, both for ligature and suture; and, as with the Austrian Germans, they have no trained nurses, the sisters doing the nursing, but the hospital control is under government management. Their operations are comparatively dry, as they use no irrigation, so that after the scalpel is taken in hand, they wipe away whatever may rise into the incision with pieces of gauze, which, by the way, I see has wholly supplanted sponges over here.

Altogether, Rome has hospital facilities for more than a thousand patients. This is an important item to those who, in going to Europe to attend the Congress, would like to blend business with pleasure, and see what the latest improvements are. The medical college is commodious, and their laboratory facilities are unsurpassed.

It may be said, in conclusion, that in the matter of language, every physician should have no trouble, at least in interpreting the many paragraphs and phrases chiselled in to marble and granite in this city at every turn, for they are all in Latin. And if one knows a little French there will be no difficulty as very many Italians speak it, besides the affinity of the Italian to the French is so great, that, with a knowledge of one, there will be but little difficulty with the other.

It has been alleged, that Rome has not accommodation for the section meetings. Those who labor under this impression are not familiar with the facilities of Rome in this respect. As a matter of fact, for a summer or spring meeting, she could, by simply roofing over the old Coliseum, provide space for forty international congresses, to hold their sessions simultaneously.

Let us hope, then, that when the time comes, America will send a full delegation to Rome. America is indebted to Italy for very much—nay, for its very name. For to-day one can go to Florence, and there see the house still standing in which Amerigo Vespucci was born. Ocean travel is rapid and swift, and railroad trains have almost annihilated space. Travel is not so very expensive. Hence, at a small outlay one will be able to take a vacation, increase his stock of knowledge, and visit one of the most beautiful countries in the world; so that, let us hope, when the hour for opening the first session of the next International Congress has arrived America will be largely represented by a delegation of physicians worthy of her.

Yours truly

THOMAS H. MANLEY, A.M., M.D.

It seems almost incredible that a half-century ago, on the occasion of the opening of the first railway in Germany, the Bavarian Medical Faculty denounced the innovation as follows: "Conveyance by means of carriages propelled by steam ought to be prohibited in the interest of public health. For the rapid motion cannot fail to create a disease of the brain among the passengers, which may be classed as a species of *delirium furiosum*. Even if travellers are prepared to run the risk, the onlookers ought by all means to be protected. The mere sight of a passing train suffices to cause the same cerebral disorder. Wherefore the authorities should insist on having a palisading of thick boards, at least five feet high, placed on each side of the permanent way."—*Bull. of Pharm.*

A HEAVY DOSE.—This is the order which a little girl brought into a Lewiston druggist's store the other day. It was written on a dirty piece of note paper, as follows: "Mister druggist: Please send speeac enough to throw up a four-year-old girl."

**OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 26, 1891 TO OCTOBER 2, 1891.**

JAMES P. KIMEALL, surgeon, U. S. A., relieved from duty at Fort Supply, I. T., and ordered to Fort Clark, Tex.

JULIUS PATZKI, U. S. A., relieved from duty at Fort Huachuca, A. T., on expiration of present sick leave, and ordered to Fort Supply, I. T.

CHARLES B. EWING, assistant surgeon, U. S. A., will continue on duty as attending surgeon and examiner of recruits, St. Louis, Mo.

WILLIAM D. CROSEY, assistant surgeon, U. S. A., relieved from duty at Fort Pembina, N. D., and ordered to Fort Missoula, Mont., for duty.

WALTER REED, captain and assistant surgeon, U. S. A., relieved from duty as attending surgeon and examiner of recruits at Baltimore, Md., and ordered to Fort Snelling, Minn., upon completion of his duties as member Army Medical Board.

**OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING OCTOBER 3, 1891.**

THOS. J. TURNER, medical director, placed on the retired list September 21, 1891.

J. H. HALL, surgeon, placed on the retired list September 23, 1891.

J. C. BOYD, surgeon, ordered to duty on Naval Medical Examining Board.

**SOCIETY NOTICE.**

**BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.**—A regular meeting of the Society will be held on Monday, October 12, 1891, at the Medical Library, 19 Boylston Place, at 8 o'clock P. M.

Dr. E. G. CUTLER, "Some Cases of Gastric Dilatation"; Dr. E. H. BRADFORD, "Aneurism of the External Iliac Artery."

G. G. SEARS, M.D., Secretary.

**APPOINTMENTS.**

LIEUT.-COL. CHARLES T. ALEXANDER, M.D., has been appointed by the President chief medical purveyor of the army, to succeed Col. Edward P. Volkmann, retired.

ROBERT T. EDES, M.D., has been appointed superintendent of the Adams Nervine Asylum.

C. IRVING FISLER, M.D., superintendent of the State Almshouse, Tewksbury, has been appointed superintendent of the Presbyterian Hospital, New York.

**RECENT DEATHS.**

PRINCE W. PAUL, M.D., M.M.S., of Boston, died suddenly in Brockton, Cal., September 29th, aged fifty.

S. S. SCHLITZ, M.D., Superintendent of the Pennsylvania State Hospital for the Insane, Danville, died September 28th, aged sixty.

WILLIAM C. ASHLER, M.D., of Atlanta, Ga., died September 30th, aged fifty-four.

PATRICIA J. MURPHY, M.D., Surgeon of the Columbia Hospital for Women, Washington, D. C., died October 3d, aged forty-seven.

SOME CONSIDERATIONS UPON LATE SYPHILIS—AND ESPECIALLY LATE HEREDITARY SYPHILIS—MORE PARTICULARLY IN ITS SURGICAL ASPECTS.<sup>1</sup>

BY ABNER POST, M.D., OF BOSTON.

In speaking of syphilis I must speak from the standpoint of the clinician and student, and not from that of the pathologist or experimentalist; nor can I hope to bring forward new discoveries or new facts. The utmost I can hope for is, that by a new presentation of facts already known, I may help to systematize our present knowledge, and to incite to new observations on a subject which can best be advanced at present by clinical study.

The help which we can expect from the pathologist is limited so long as the pathognomonic entity of syphilis is unknown to us. Help from the experimentalist is wanting, since the lower animals are practically exempt from the disease, and experiment on human beings is not justified. I shall confine my remarks to such portions of the general subject as have been of special interest to myself, and it may be possible to designate certain points where study is specially desirable.

I wish particularly to draw attention to that class of cases known as late hereditary syphilis. By this term it is intended to designate syphilitics who have inherited the disease from their parents, and who have survived the early years of life in a state of more or less good health, only to show, after a lapse of years, symptoms which correspond to the late, or tertiary, symptoms of acquired syphilis. The interval after which late symptoms show themselves in congenital cases may be longer or shorter, exactly as in acquired disease. The disease may be entirely latent during the interval between the early and late symptoms, or it may have shown itself more or less distinctly. The late forms of hereditary disease are especially worthy of study, because they are not thoroughly known; the boundary lines between hereditary syphilis, rickets and tuberculosis are clinically ill-defined.

On the whole, it cannot be far from the truth to say that we have been, and I fear we are still, too slow to accept the diagnosis of syphilis in children after the age of infancy. Children with lesions that in adults would be recognized as syphilitic, or at least as suspicious, are too often classed as scrofulous, without a thought apparently of other diagnosis. There are certain children of this class who are so distinctly marked that mistake seems impossible; the sunken nose, the destroyed palate, the triad of Hutchinson, notched upper incisors, opaque cornea with defective hearing, present a clinical total that cannot be mistaken. But all subjects of inherited syphilis are not thus marked. Other cases there are in comparative abundance, which we too easily overlook.

These late hereditary cases may be considered with advantage at the same time with the acquired cases.

All authors agree that the later forms of acquired syphilis are not, of necessity, a part of every case. Every physician whose life has been long enough to give him a perspective, must have cases in mind in which the later lesions have been wanting through

long lives. Men of seventy-five and eighty rise to my mind, who must have had syphilis in their youth, who have had no other reminder of the disease than that dread of the consequences which renders miserable so many lives. Yet every doctor of experience must also have been disappointed at seeing late symptoms appear in patients who had been under his own treatment for a long time. The comparative number of cases in which the tertiary symptoms appear it is impossible to estimate. As regards the future of the youth who acquire syphilis, the greatest difference of opinion exists. On the one side, for example, is the opinion of Hutchinson<sup>2</sup> as given in a recent article, in which occurs the following statement: "I do not think that an insurance office would do a bad business if it were to undertake at ordinary rates young men in the early stages of syphilis. Judging from my own experience, they appear quite as likely to live long as others, and [as I have already said] the effect of treatment seems to be, in not a few instances, to improve the health rather than otherwise."

In the same article he refers to the great number of medical men he has treated for chancres acquired in the practice of our profession. In many of these cases the patient has remained under his observation for a great number of years. Of these men he says, "Several are of course dead, but I can scarcely call to mind a single one in which death, or, indeed, any material damage to the general health resulted from syphilis. In a large majority of cases these patients have, so far as I am aware, suffered nothing since getting rid of their early symptoms, and are at present in excellent health."

As an extreme contrast, one may quote on the other hand the opinion of Dr. W. R. Gowers, Lettsonian Lectures, *Lancet*, February 16, 1889: "A general survey of the treatment of syphilis, as well as the observation of individual cases, can scarcely fail to impress one important conclusion on an impartial observer. It is not easy to state this conclusion in language not open to misconstruction. In its broadest form the conclusion is, that syphilis is an incurable disease. In the form least liable to misinterpretation, and free from inexactness, it is this: There is no real evidence that the disease ever is or has been cured [the word disease being here used to designate that which causes various manifestations of the malady]."

But even the holders of the extremest views of the incurability of the disease do not regard its appearance in tertiary form as an integral part of the disease.

The relative frequency of tertiary syphilis was discussed at the Congress of Dermatology and Syphilography held in Paris in 1889, and naturally approximate opinions only were expressed.

Drysdale considered that about eight per cent. of syphilitics show late lesions when untreated.

Mauriac would put it somewhere between five and twenty per cent.

Haslund, of Copenhagen, gave the comparative numbers of the cases of secondary and late, or tertiary disease, that he had treated in hospital service, and the cases which he classed as tertiary amounted to ten per cent. (9.9) of the whole number.

Vajda, of Vienna, quoted some very interesting figures from the statistics of the Vienna General Hospital for the period of ten years, from 1868 to 1877.

<sup>1</sup> Read before the Congress of American Physicians and Surgeons, Washington, September 23, 1891.

<sup>2</sup> The Modern Treatment of Syphilis. The Practitioner, June, 1891, p. 411.

Of the total number of cases (198,718) admitted to the hospital during that decennial period, 4.7 per cent. (9,739) were syphilites. Of the syphilites, 6.8 per cent. (632) were the victims of tertiary lesions, or three per cent. of the general admissions, a percentage which the author, Vajta, believes to be 20 per cent. below the truth. Certainly, the term late lesions as used in the first part of that decade, would not include certain diseases of the nervous system, which, at that time, were not fully recognized as syphilitic.

Valuable as are the figures that attempt to give some sort of an answer to the question of the frequency of late syphilis, and to calculate the percentage of cases of syphilis that show late symptoms, the most valuable contribution from that Congress to our knowledge on the subject lies in the figures of Fournier, which show that in point of time by far the largest number of cases of late syphilis occur in the third year after inoculation, that from the third year on the number diminishes, and that after the tenth year it may be considered rare.

Taken in periods of five years Fournier's late cases run as follows:

First five years	. . . . .	1,023 cases
Second "	. . . . .	700 "
Third "	. . . . .	322 "
Fourth "	. . . . .	211 "
Fifth "	. . . . .	68 "
Sixth "	. . . . .	31 "
Seventh "	. . . . .	13 "
Eighth "	. . . . .	12 "

Single cases occurred in the 41st, 43d, 52d, 54th, and 55th years, making the total of 2,395 cases tabulated.

Of course, an enumeration that makes many late symptoms occur during the first five years is based upon the character of the lesion rather than upon the time of its occurrence.

It seems unnecessary to enumerate the lesions generally included under the head of late lesions, but these figures indicate that the so-called late lesions occur much earlier in the history of the disease than we are in the habit of thinking. So far as the figures go, the French Congress affords us ground for a more definite prognosis than we have hitherto possessed. We seem to be justified in saying that, after the third year, the chances of a recurrence grow steadily less, and that probably only one case in five, or 20 per cent., shows the dreaded late troubles.

These figures embolden me to say that it is my impression that outbreaks of late symptoms in congenital syphilis are of earlier occurrence than is usually supposed. The age of puberty is the time at which such outbreaks are expected. I have no figures to confirm my opinion, but I have learned to think that it is very common for hereditary disease to show its late features as early as the 1th, 5th, or 6th years. But it must also be said of these cases that their life histories are seldom complete with the story of a single outbreak.

There is one other matter in connection with these figures to which it seems proper to refer. Syphilographers are sometimes accused of so extending the field of syphilis as practically to include all pathology.

In the General Hospital of Vienna where syphilis holds a prominent place, according to the official report for ten years from 1868 to 1877 inclusive, but 4.7 per cent. of the whole number were syphilitic, and but three tenths of one per cent. of the whole were cases of late syphilis. Even increased by 20 per cent. a *Verdick* proper, the number still remains smaller

than would have been supposed. Incidentally, I may say here, that the Autopsy Records of the Boston City Hospital which contain accounts of approximately 1,700 post-mortem examinations, contain but nineteen cases which permit a student of these records to affirm from the words of the pathologist a pathological diagnosis of syphilis.

It is interesting to inquire if we are able to prevent the outbreak of late symptoms. As a preventive of late symptoms, early treatment by mercurials is ranked high—deservedly so far as we can see—and still it must have fallen to all of us to see cases which have been treated with care show late and grave symptoms. Most of the cases with late symptoms of which I have known the earlier history, have been late in coming under treatment, or there has been some fault in the therapeutic measures, as, to take a single instance, in a case of syphilitic hemiplegia which comes forcibly before me, the disease had existed for a year before it was recognized and treatment begun. It may be said of such cases that the disease has been allowed to get the upper-hand before the check was applied, or that they are like the early malignant cases that occasionally show themselves and defy treatment; but, still pride ourselves as we may on the effect of our interference, no method of treatment is free from relapses so far as I can discover. Syphilographers who come in contact with syphilites who have been faithfully treated by different methods in other countries, as well as in our own, see occasional relapses after all methods. No method exists that will allow us to promise a cure, that is, an absolute immunity from the danger of subsequent attacks. It is in the nature of the disease to show relapses and late symptoms. When I speak thus despondently as to the uncertainty of treatment, I refer only to the late symptoms. But I mean to say that our present attitude towards mercurial medication is a matter of opinion simply. We believe that mercurial treatment acts as a preventive of later symptoms: a belief held I know not how long. Benjamin Bell expressed it in strong terms, but it cannot as yet be proved. The efficacy of treatment by mercurials has been established clinically since before the days of Paracelsus; the efficacy of mercurials in destroying microbes seems a sufficient explanation of its clinical action. We are then justified in supposing that more accurate pathological knowledge will allow us in the future to apply more effectively the drug we use so efficiently it somewhat empirically, now.

In thinking of late syphilis there are certain questions that almost of necessity arise in the mind. Of these the first regards its contagiousness. Are the late lesions of syphilis inoculable? Certainly the contagiousness of late symptoms must be slight, if it exists at all. I have among my own acquaintance two cases in which the disease was communicated to the wife two and one-half years after the reception of the disease by the husband. That is the latest infection which I can vouch for of my own personal knowledge, but Fournier mentions a case of infection in the sixth year. But here we meet with practical difficulty in reconciling our various statements that late lesions are not inoculable. The inoculability does extend to two and a half years, and may [exceptionally] still exist at the great length of six years; the greatest frequency of late lesions, so called, is found in the first five years. When we say that late lesions are not inoculable the proper meaning of the word late must be preserved.

The power of transmitting the disease to offspring remains long after the power of direct inoculation seems lost; but here, as in other manifestations, the disease shows its singular habit of fixing particularly upon special organs or systems. The general law of syphilitic heredity is a diminution in the activity of the virus, so that successive children show less emphatically the effects of the disease. Occasionally, however, we see a whole series of children follow one another, each with little or no apparent diminution of the virus. Almost at the moment of writing this sentence I was asked to see a syphilitic child which presented characteristic snuffles, loss of eyebrows, enlarged glands, fissures and ulcerations of the lips and anus, with sarcocele of both testes. The first child of the mother was born twelve years ago at seven months, and quickly died. Miscarriages and still-births have followed at various intervals, but no child that has survived. This child is the first by a second husband, but seems only another of the series. No questions elicit any certain proof of disease in mother or either husband.

These series of children born so markedly syphilitic are exceptional, and illustrate one of the marked peculiarities of syphilis, namely, its habit of fixing upon some system or systems in each of its victims, and expending its force chiefly upon that system. Thus in one patient the skin will show the deepest lesions, and for years the disease will repeat its cutaneous outbreaks. In another, the bones will form the chief object of attack.

I propose to say a few words in regard to several of the different systems.

Induration and enlargement of the lymphatic glands is one of the most common and characteristic symptoms of early syphilis. Beginning in the immediate vicinity of the original point of inoculation, at the time of the first outbreak of constitutional symptoms it becomes general, until in well-marked cases all the superficial lymphatics are found to be engorged. At the end of the acute stage these glands have resumed their normal condition. The relation of the lymphatic glandular system to the later outbreaks of the disease is entirely different. Engorgement of the subcutaneous glands is invaluable as a diagnostic sign in early syphilis; in late syphilis it is exceptional and almost without diagnostic value, but, according to Lancereaux, the affections of the visceral glands must be reckoned among the most constant alterations of tertiary syphilis. They bear the same relation to visceral syphilis that swelling of the subcutaneous glands bears to syphilis of the skin, that is, they are a necessary concomitant. Of subcutaneous glands late syphilis is said to occur most frequently in the inguinal, and next in frequency in the glands of the neck, especially the submaxillary and supraclavicular. In other glands its occurrence is much more rare. At first the glands are in general enlarged, indolent, movable upon each other; after a time firm cicatricial tissue fixes them to one another, and binds them to the parts beneath. If the glands soften and break down, the skin is usually involved. If the glandular gummata are concomitant with characteristic signs of syphilis they will readily be understood, but when they occur alone diagnosis is difficult and even impossible. I suppose every large surgical service presents several cases annually of enlarged glands of the neck, demanding treatment at the hands of the surgeon by the knife. The majority of the cases are evidently tubercular, and show suppuration, sometimes caseation. It has been

my custom where anything in the history of the patient, or any cicatrix on the body allowed the least suspicion of a syphilis, to administer the iodides before proceeding to operation. In rare cases resolution has followed, and disappearance of the tumor. I have allowed myself to feel that in some of these cases there was a syphilitic taint. The cases are rare, but they certainly exist.

In late hereditary syphilis the part played by lymphatic glands is greater, though hardly more diagnostic. It is exceedingly common to find cervical glands enlarged in congenital cases, but not always in a form that by analogy with acquired cases would be called characteristic, and by no means so generally as so give them the diagnostic value of the enlarged glands of the early stages. Glands are often enlarged especially in the anterior cervical region, and remain indolent and painless for several years. In this form they do not assume the large size of tubercular forms, but they are generally large enough to rise above the normal level of the skin, and be evident to the sight.

In some cases suppuration takes place, and the most troublesome cases of all are those in which syphilis and tuberculosis coexist upon the same individual. This glandular engorgement renders the distinction between the serofulous cases, so common in New England, and hereditary syphilis exceedingly difficult, and clinically in many cases absolutely impossible; but it is a fatal error to accept every case of enlarged glands of the neck in children without question as tuberculous.

Probably one reason, why in certain cases it is impossible to distinguish between late hereditary syphilis and tubercular disease of the glands of the neck, is because the two diseases coexist in the same individual. These are the cases in which the glands reach large size, suppurate, and perhaps coexist with bony disease, etc.

The syphilitic glandular tumors of inherited syphilis improve very greatly under appropriate antisymphilitic treatment, but very little under cod liver oil.

Cutaneous lesions are second in frequency to the lesions of the nervous system in late acquired disease. Of their ordinary occurrence there is little to say. There is a class of cases, the cutaneous and subcutaneous gummata, which may perhaps be particularly mentioned because of their resemblance in certain situations to other lesions. The ulcerating gumma is by no means infrequent in positions usually occupied by the primary sore, nor is it infrequent to mistake it for the primary sore, so nearly does its induration counterfeit the primary.

I remember distinctly a sore which I mistook for a primary inoculation until I learned that the patient was under treatment for syphilis by one of my most respected colleagues, and that the sore in question had come on without exposure. These cases are fairly well known at present, but so closely do they counterfeit the primary as to throw a shadow of doubt over some at least of the reported cases of reinfection.

On the lips such cases give rise to some difficulty of diagnosis, a difficulty which is aggravated rather than lessened by the too frequent application of caustics. It is here that the gumma resembles epithelioma, and is more likely to be mistaken for malignant disease than for a primary sore, but it is fortunately amenable to treatment by iodides.

Fournier speaks of a late roseola which has attracted his attention, in which the macula has a rosy aspect, and a circular contour with an unaltered centre. "For twenty years," he says, "I have seen from time to time manifestations of this character, and I have resisted the idea of calling them syphilitic; but as like cases continued to produce themselves in syphilis I finished by thinking that we have to do with a manifestation really syphilitic; with a sort of late, if not tertiary roseola."

Such a phenomena I have observed a few times. The efflorescence is interesting as an observation, and particularly because so superficial a lesion is not usual among late manifestations. It helps to break down the boundary line already so difficult to define between secondary and so-called late symptoms.

The skin lesions of late hereditary syphilis must be less frequent than those of adult acquired disease, or at least less characteristic. The round ulcers on the legs, or the smaller circular ulcerations about the head of the tibia, or generally in the vicinity of the knee-joint do occur in children, and so-called syphilitic lupus has been recorded several times.

Most of the supposed late hereditary cases that have shown skin lesions under my observation have had tubercular ulcerations of rather irregular character which may possibly have been tuberculous. The boundary line between the ulceration of tubercle and of late hereditary syphilis is yet to be established.

In speaking of the bones, I wish to ask how trustworthy is nocturnal osteoscopic pain as a symptom of syphilis? Its extreme value is undisputed, but I believe it ought not to be considered alone as *absolutely reliable*, especially if it is referred to spots which are only exceptionally attacked by syphilis, or in other words, it is *not impossible* that pain from other causes may be nocturnal in character. As a working diagnosis the conclusion of syphilis from nocturnal pain alone may be proper, but as a positive diagnosis which shall follow the patient through life it is insufficient; and yet I think men are allowed to suffer in reputation and in purse for a diagnosis made on such slender ground.

But if too great weight is sometimes given to nocturnal pain, on other occasions it is shunned even as a working hypothesis, when it ought to be made. The syphilitic pains of children are not sufficiently known, and may be the occasion of grave errors of diagnosis. Rheumatism and "growing pains" are called on to account for them. Many children have been treated in vain for a long time, who have rapidly recovered by the administration of the iodides.

In those cases of bone disease, especially among children, which come to operation, it is rare to find the surgeon supplement the use of his knife and gouge with internal medication. It occasionally happens that disease of the bones spreads after the removal of the diseased portion, to the surprise of the surgeon, and the discredit of his art, because he has failed to see the necessity of medication in cases of syphilitic origin, or, because if he desires to use internal remedies, he is satisfied with cod liver oil.

Disease that attacks several of the long bones simultaneously, or nearly simultaneously, should arouse the suspicion of syphilis, and particularly if one or both tibiae are among the bones attacked. To say that it should arouse suspicion is putting it very mildly, at the same time, it would be going further than circum-

stances warrant to say that such a case was of necessity syphilitic.

A marked difference between tuberculosis and syphilis lies in the preference for syphilis for the long bones and their shafts, while tuberculosis attacks by preference such bones as those of the wrist and ankle.

As to diseases of the joints, they are indisputably at times the result of syphilis; but I must confess that, so far as the joint alone is concerned, in the few cases I have seen, the symptoms are hardly characteristic. Whereas, lesions of the bones themselves in their continuity in children are likely to be syphilitic, lesions of the joints are more apt to be tuberculous. In a long list of cases of hereditary syphilis Fournier reports but five cases of joint disease to eighty-two of bone disease.

Of course, no reference is here made to the cases of separation of the epiphysis known as Parrot's disease; nor to the peri-articular nodes and gummatas which simulate disease of the joint itself.

Syphilitic disease which involves the breast has recently attracted some attention. Its usual time of appearance is quite late, but like other late forms of disease it may occur quite early, as in a case of Ambrosoli,<sup>1</sup> in which one breast was smaller and hard very soon after the first appearance of secondary symptoms. Swelling of the second breast followed, and both returned to normal size under the use of iodides. Apparently syphilitic disease may either manifest itself as a diffuse enlargement of the gland or as a separate gumma; in the latter case it conducts itself as do gummatas in other situations. The disease occurs in men as well as in women and in hereditary as well as in congenital cases. This form of syphilis is unusual, but it has occurred in the practice of two of my friends.

(To be continued.)

## A CONTRIBUTION TO THE TREATMENT OF RUPTURE OF THE BLADDER.<sup>1</sup>

BY A. T. CABOT, A.M., M.D., OF BOSTON,  
Surgeon to the Massachusetts General Hospital.

SINCE the appearance of Mr. Rivington's monograph upon "Rupture of the Bladder," in 1884, a number of cases of intra-peritoneal rupture of the bladder have been treated by laparotomy and suture of the rent. The success which has attended these cases, and also the many instances of repair of bladders wounded during laparotomy, have gone far to establish the rule laid down by Mr. Rivington that when an intra-peritoneal rupture is made out, an immediate laparotomy should be done. The importance of early interference in these intra-peritoneal cases is so evident, that a surgeon procrastinating an operation even for a few hours cannot easily find justification for his delay.

It not infrequently happens, however, that the first symptoms of bladder rupture do not clearly show whether the rent is intra- or extra-peritoneal, and the delay necessary to settle this point allows time for an inflammation to gather headway, which operative measures are afterwards powerless to check. It is the purpose of this paper to consider the conditions of extra-peritoneal ruptures of the bladder, and to formulate,

<sup>1</sup> Read before the American Association of Andrology and Syphilology, Washington, September 23, 1891.

<sup>2</sup> Gazzetta med. e. Ital., Lombardia, 1881. Quoted by Newman.

if possible, rules for operative procedure, which can be applied early, without waiting for an exact diagnosis.

Usually the symptoms of rupture of the bladder are tolerably distinct, and it is not intended here to go into a consideration of them, for they have been thoroughly described in many treatises and articles on the subject. As, however, it is important, before undertaking any operative procedure to demonstrate beyond doubt, if possible, the existence of the lesion for which the operation is done, I wish to speak of the only physical test that seems to me to offer confirmatory evidence at all conclusive of bladder rupture. I refer to the injection of fluid which afterwards does not return through the catheter. This method, suggested by Dr. Weir, has served the writer well on two occasions in establishing the diagnosis of rupture of the bladder, and twice in excluding the bladder in a general injury of the abdomen, which caused a profuse hamaturia.

In order that the evidence obtained by this method shall be reliable, the injection should be repeated several times, and care must be taken that the catheter lies well in the bladder, and that it is not occluded by clots. With attention to these particulars, if the boric solution injected does not all return, it is conclusive evidence of rupture of the bladder. Sometimes, especially in intra-peritoneal rupture, more fluid returns than is injected, and at the next injection the amount returned may be less than that thrown in. Such variations are very conclusive of rupture.

The only conditions under which this test might fail to demonstrate a rupture that existed would be when the rent was so small that no considerable extravasation of the bladder contents could take place, and in case of a valvular closure of the bladder wound, as occurred in one case through the prolapse of a coil of intestine into it.

Dr. Keen has suggested the substitution of air for water in this test, and says that if no rupture has occurred, the bladder will appear in the hypogastrium as a rounded tympanitic tumor, while, if there be a rupture, the air will fill the general peritoneal cavity. In this he only takes into account intra-peritoneal ruptures, and might altogether miss the detection of an extra-peritoneal rent. Also the gas does not admit of such exact measurement as a fluid.

Suppose now that the evidence of rupture of the bladder is distinct, and that the injection of fluid has confirmed this diagnosis, but there is still doubt whether the rupture is into the peritoneal cavity or not. The practice hitherto has been to endeavor to proceed in such a way that if the rupture is extra-peritoneal, that fact shall be found out before the peritoneal cavity is opened. This plan was adopted when the peritoneal cavity was viewed with an awe that has gradually disappeared as we have become more familiar with its tolerance of manipulation, and the fear of unnecessarily injuring the peritoneum, with the desire for an accurate diagnosis before proceeding to operation, has often led to delays which have been fatal, by allowing time for a serious inflammation to be set up.

It would seem, therefore, worth while to open the subject anew, and see whether with our modern views we find any reason for changing the older practice.

The object which the surgeon has in view in approaching an extra-peritoneal rupture is to provide adequate drainage for the urine which escapes from the bladder, and not to close the opening. Ordinarily, these extra-peritoneal rents are inaccessible to the ap-

plication of sutures, and even in those cases of anterior ruptures where sutures could be placed, the tissues, infiltrated with urine, are not in a condition favorable for healing, and the danger of secondary extravasation of urine would be great.

Some writers advise that cases of extra-peritoneal rupture shall be treated by simple drainage of the bladder, either through a perineal wound, or by a retained catheter (*sonde à demeure*). While this plan may be sufficient to prevent any further extravasation of urine, it evidently affords very insufficient drainage for the urine which has already escaped into the tissues, and affords no adequate outlet for the pus and masses of sloughing tissue, which are certain to follow from the contact of the urine. It is therefore a very uncertain method, leaves the result mainly to chance, and has not been followed by a measure of success sufficient to recommend it. It is generally accepted, therefore, that drainage of the urine that has escaped from the bladder is a prime necessity.

In order then to treat an extra-peritoneal rupture in the best way, it is important that the operator should know where the rent is, and in what direction the urine is forcing its way through the loose peri-vesical connective tissue. If he has this knowledge, he can make an opening into the extravasation from the nearest available point on the surface, and can establish the most direct drainage possible. Without this knowledge he has to make his operation gropingly, and even if he reaches the extravasated urine, he may so place his tubes that the drainage is only partial and ineffectual.

A study of the reported cases of extra-peritoneal ruptures shows that the urine may be effused in several directions. It may infiltrate up beneath the peritoneum on the anterior wall of the abdomen; it may fill the tissues about the neck of the bladder; or it may escape beneath the peritoneum on one side or the other of the pelvis, and run up in the loose connective tissue towards the kidney. It is usually impossible to tell from the early symptoms, in which of these directions the effusion is to be looked for, and, indeed, it may extend in two or three directions at once.

Mr. Rivington has suggested that in cases where a doubt exists whether the rent is intra-peritoneal or extra-peritoneal, an incision shall be made into the prevesical space, and if no rupture is found in that quarter, that the peritoneum shall then be opened. The disadvantage of this plan is that if any effusion of urine is found in the prevesical space, it is impossible to tell without a good deal of separation of the tissues whether it extends down on one side or the other towards the back of the pelvis, or whether, as has happened in many of the reported cases, there has been more than one rupture, or yet, on the correct appreciation of these points depends the intelligent placing of the drainage-tubes, upon which success or failure depends. It seems, therefore, as if this incision would often leave us uninformed on important points even when the effusion is found.

Moreover, if an effusion is opened in the prevesical space, and it then becomes necessary to open the abdomen to treat an intra-peritoneal rupture, or to get a fuller understanding of the case, the operator is placed in the unpleasant position of having to open a urinary extravasation directly into the peritoneal cavity, and it will afterwards be difficult to so closely suture the peritoneal wound that no infection shall take place through it.

The cases in which the prevesical incision is applicable are those in which the rupture is in the front wall of the bladder, just above the prostate, and in which the effusion is small or circumscribed. Unfortunately, it is not often possible to diagnose these cases before operation, though this condition may be suspected when there is fracture of the pubes with pain and tenderness confined to the hypogastric region.

In Dr. Weir's case, which was of this sort, the symptoms were of moderate severity, and for forty-eight hours the injury was "considered as a slight urethral laceration." On the fourth day, when the operation was done, the circumscribed effusion above the pubes could be made out by percussion, and the incision was made directly into it.

Another plan proposed is to make a median cystotomy, and with the finger in the bladder to search for the rents. Harrison and Weir advocate this measure, but in a case in which Mr. Harrison applied it, a second rupture in the trigone went undetected; and it is plain that an intra-vesical exploration, even if the rents are found, will not tell us in what direction the urine is forcing its way through the tissues, and consequently leaves us in doubt as to where the drainage should be placed. So that unless we mean to rely on the simple perineal drainage of the bladder in all extra-peritoneal ruptures, we shall often be left in doubt as to the further treatment of the case even after exploration of the bladder.

How can we then best obtain a knowledge of the condition of things in a doubtful case of extra-peritoneal rupture, and so put ourselves in a position to act understandingly and efficiently? I think that this knowledge can best be gained by opening the abdominal cavity, and so getting an opportunity to thoroughly inspect and palpate the parts about the bladder.

A simple exploratory incision into the abdomen carries with it a mortality risk of from one to three per cent., while the information gained by such an inspection enables us to treat the case with so much more directness and thoroughness that we increase the patient's chances of recovery vastly more than we jeopardize them by the abdominal opening.

The following case is reported to illustrate this point: D. P. W., a strong man of about fifty-five, was seen by me in June, 1890. He had been suffering through the winter from frequent and painful micturition, and up to the time I saw him had been passing water almost continuously, the intervals being but a few minutes in length.

Upon examination a stone was to be felt in the membranous urethra, both with the sound and with the finger in the rectum.

June 6th, he was etherized for operation. A large sound was passed, and with it the stone was easily pushed back into the bladder. A boric solution was then injected preparatory to doing a litholapaxy. The injection was strongly resisted by the bladder, which was closely contracted, and the water escaped around the catheter as fast as it was thrown in. After the ether narcosis was more profound, a rubber band was tied lightly around the penis to keep the water from escaping. An ounce and one-half of boric solution by means of a syringe was then injected, and the lithotrite was introduced. The stone was caught at the first attempt. It was very small, and required but one crushing to entirely remove it to fragments. While the lithotrite was in, it was noticed that the bladder contracted

strongly, forcing some drops of water out along the groove of the instrument. The lithotrite was then withdrawn, and the tube for washing out the bladder was introduced.

It was quickly found that while the water could be easily injected into the bladder, none of it returned, so that it presently became evident that there must be a rupture of the bladder allowing the solution to escape from it. It was at once decided to do a laparotomy in order to discover if possible where the rent was, and to repair it if it was found to be intra-peritoneal. An opening was made in the middle line, midway between the umbilicus and the pubes. There was no fluid in the peritoneal cavity, and upon examining the region about the bladder it was found that the sub-peritoneal cellular tissue lying behind the bladder and running up towards the left side of the pelvis was distended with fluid. A small bit of gravel could be detected in the loose tissue behind the bladder.

It was evident that this collection of fluid ought to be drained behind the peritoneum, and after its extent and distribution had been accurately made out, the abdominal wound was closed with sutures, and sealed with iodoform gauze and collodion. An opening was then made in the left inguinal region, such as would be used for tying the common iliac artery. Through this the peritoneum was pushed up with the finger until the space behind the bladder was reached. Fluid, colored with blood, began at once to escape in considerable quantities through this wound. A drainage-tube was introduced into the pelvis behind the bladder, with a bend in it where it passed over the iliac vessels, which were so exposed to the pressure of the tube that fears were entertained of their sloughing under it.

The patient was then put into the lithotomy position, an opening was made into the membranous urethra, and through this a tube was introduced into the bladder for perineal drainage. The finger introduced into the bladder felt a trabeculated, closely contracted cavity, but the exact locality of the rent could not be detected. A few fragments of gravel were removed. The tube in the perineal wound was attached to a longer tube which ran over the side of the bed into a bottle, and through this the urine drained very satisfactorily.

The cavity in the pelvis soon began to suppurate profusely, and to discharge many large shreds of sloughing, connective tissue. The tube was taken out after a few days, and the wound was irrigated two or three times a day. During the first few weeks injections made into the bladder escaped through the opening in the side. When the sloughs ceased coming, and the cavity dwindled down to a deep fistulous track, a small tube was inserted, and this was gradually shortened as the parts healed behind it.

It was not until March, 1891, that the opening in the groin finally closed, and the perineal tube was taken out for good. This change might probably have been made sooner, but was delayed on account of the timidity of the patient. The bladder was naturally small after such long drainage, but no smaller than it had been before the operation. He was able to hold his water only half an hour. He himself was in better condition than he had been for years, and during the spring of 1891 weighed more than he ever did in his life.

In June a little gravel was discharged through the

perineal opening, relieving some discomfort from which he had been suffering for about a month.

The rupture in this case was probably caused by the violent contractions of the bladder when the exit of the urine through the urethra was obstructed, and was undoubtedly due to the giving away of some thin-walled diverticulum, or hernial pouch of mucous membranes, projecting between the bundles of the hypertrophied muscular coat. The manipulation of the lithotrite was perfectly easy, I felt sure that the wall of the bladder was not caught in it, and although the rupture may have occurred at the first compression of the litholapaxy bulb, yet the water entered the bladder so easily as to occasion surprise, and to make me think that the rupture had already taken place. The case is a warning against the use of force in injecting even a small quantity of water into a diseased bladder.

In this case the necessity for prompt action, and the impossibility of making, upon an etherized patient, a diagnosis between an intra- and an extra-peritoneal rupture compelled us to resort to an incision into the abdomen in order to find out what we had to deal with.

The moment we had made this inspection the case was clear, and we were able to proceed intelligently to remedy the unfortunate condition.

The certainty with which we could proceed after the abdominal incision, was in such marked contrast to the condition of uncertainty before, that the question at once arose: Is not an exploratory laparotomy often a necessary first step to the intelligent treatment of extra- as well as of intra-peritoneal ruptures of the bladder?

A study of the literature of extra-peritoneal rupture of the bladder has led to the feeling that this question should be answered in the affirmative, and I believe that in many such cases a preliminary exploration of this sort will furnish information that will greatly better the chances of recovery.

I would suggest then, for your consideration, the following rules:

(1) When an intra-peritoneal rupture is made out, an immediate laparotomy, with suture of the bladder wound and subsequent drainage of the bladder should be done.

(2) When a reasonable doubt exists as to whether the rupture is intra-peritoneal or not, an immediate laparotomy should be done.

(3) If an extra-peritoneal rupture is made out, and uncertainty exists as to the direction in which the urine is extravasated, a laparotomy should be done for exploration to ascertain how the drainage may best be placed.

(4) In the case of fracture of the pubes with evidence that urine is extravasated in the prevesical space, an incision should be made in the suprapubic region, a tube should be carried to the bottom of the effusion, and a median or lateral lithotomy should be done for drainage of the bladder.

Exception. Occasionally, in cases of severe injury with much shock, when a long operation could not be borne, a median lithotomy may be hastily done for drainage, and the opportunity may be taken for exploration of the position of the rent, to serve as a guide for further interference in case the patient rallies sufficiently.

In short, a laparotomy should be done in all cases

of bladder rupture except those that come under Rule 4, or those of such severity that they cannot bear more than the median operation.

These rules designed for the furtherance of early operations are only intended to apply to cases seen in the early stages. After the first few days, if the patient survives, other indications may arise to guide the operator. The urine effused may be seeking the surface at some point, and the surgeon's duty is then to open the urinary abscess, and to provide drainage for it and for the bladder.

Rule 1 embodies the already established practice. If Rules 2 and 3 are accepted, they will encourage early operations in cases where, if exact indications were waited for, the operation would probably be done too late.

Lastly, comes the question of where to make the incision, and how to place the tubes for the best drainage of effusions in different parts of the pelvis. If the effusion is in front of the neck of the bladder, and the opening has been made into it by the suprapubic incision without opening the peritoneum, the bottom of the effusion should be sought with the finger, and a drainage-tube carried down to it.

In opening the bladder for drainage in such a case it may be worth while, if there is evidence that the effusion is making its way backward, to make the lateral perineal cystostomy rather than the median, because in the lateral incision the parts about the neck of the bladder are more freely opened, and if the urine finds its way in that direction, it is afforded a sufficient outlet. By the median operation, unless the incision is carried back into the prostate, there is danger that the parts behind the triangular ligament will not be thoroughly laid open, and that any urine which found its way in that direction might not freely escape.

When, as so often happens, the effusion finds its way along the loose tissue on the side of the pelvis, and as in the case reported in this paper, up along the iliac vessels towards the renal region, perhaps no better incision can be chosen than that which is used for tying the common iliac vessels. In order to give the most direct drainage, and at the same time not to have any more pressure from the tube upon the iliac vessels than can be helped, the incision had better be made rather more towards the median line of the abdomen than is usually done for tying the iliac artery. In this way the tube goes down more directly, and does not make so sharp a bend where it dips into the pelvis over the vessels. If, however, the effusion has already reached up behind the peritoneum, above the brim of the pelvis, the incision must be made further out near the anterior superior spine of the ilium in order to give the best drainage. The finger introduced from this region can penetrate quite readily over the brim of the pelvis, and well down behind the bladder, while the peritoneum separates so easily that a considerable channel can be made, through which the sloughing connective tissue can afterwards discharge itself. Ordinarily, these anterior openings afford tolerably satisfactory drainage for pelvic abscesses, as the intra-abdominal pressure is sufficient to force out the pus even through an unfavorably placed opening.

In any case in which a suppurating cavity has formed in the bottom of the pelvis, which does not drain satisfactorily through an anterior opening, it is perfectly possible to reach it, and give it good drainage, by adopting the incision usually employed for

excision of the rectum, and removing the coecyx and one side of the lower segment of the sacrum. Such a wound as this, which bears the name of Kraske, who uses it for excision of the rectum, gives thorough access to the lower part of the pelvis, and would give excellent dependent drainage in case of an abscess which was burrowing in that region, and which did not sufficiently discharge itself through the more anterior openings.

## PENETRATING PISTOL-SHOT WOUNDS OF THE SKULL<sup>1</sup>

BY E. H. GRADFORD, M.D., AND H. L. SMITH, M.D., BOSTON.

PENETRATING pistol-shot wounds of the skull constitute surgical lesions, which need for their treatment strict rules of procedure, as the cases are exceedingly grave, not very frequent in the experience of many surgeons, and involve great responsibilities. Against surgical interference may be urged the fact that the chances of benefit are very slight; in favor, the general surgical instinct which prompts attempting whatever offers a possibility of success in cases where death seems certain. The number of instances where surgical interference has resulted successfully are comparatively few, and the fact that many cases have recovered without operation suggests that the improvement in these instances may have been due to accidental causes and not surgical intervention. The question, therefore, is a pertinent one, whether from the point of view of recent surgery operative interference offers better chances of recovery than non-intervention.

In drawing conclusions from the recorded facts, it is necessary to distinguish between gun-shot wounds of war and pistol-shot wounds of civil life. For, although there are no statistics to prove the fact, it is reasonable to imagine that injury from a rifle ball will be greater than that from a ball of smaller calibre. The exact mortality from rifle-shot wounds of the skull cannot be determined, as by far the greater number of them in the war died on the field without record. This is also true, to a certain extent, in civil life, as those who are killed instantly are not brought to the hospitals, but cases of instantaneous death from pistol-shot wounds must be rare, and in the majority of cases surgical treatment of some sort is solicited; and for this reason the hospital statistics for pistol-shot wounds may be considered as of accuracy in representing the mortality of this class of wounds. If, therefore, there is a possibility of recovery from gun-shot wounds or penetrating and perforating gun-shot wounds of the skull, as is well established, it is probable that the prospect of such recovery is greater in pistol-shot wounds of the skull.

The most historic case of this class of injury is one which brought such calamity to the nation that the surgical details were overlooked, and are not generally known. The surgical facts may be found in the "Medical History of the War of the Rebellion," Part I, Surgical Volume, page 305, classed among the gun-shot wounds of the skull. They are of surgical interest, and deserve careful perusal. The following is extracted from the report of the case:

A. L., aged fifty-six years, was shot in the head at Washington, on the evening of April 14, 1865, by a large, round ball from a Derringer pistol in the hands

of an assassin. The wounded man was found "in a profoundly comatose condition," the breathing "exceeding stertorous."

Dr. Leale writes: "No pulsation was perceptible at the right wrist. When the head was examined, I passed my fingers over a large, firm clot of blood, situated about one inch below the superior curved line of the occipital bone and an inch and a half to the left of the median line of the same bone. The coagulum I easily removed, and passed the little finger of my left hand through the perfectly smooth opening made by the ball, and found that it had entered the encephalon. As soon as I removed my finger, a slight oozing of blood followed, and his breathing became more regular and less stertorous. After the administration of a small quantity of brandy and water, of which a mouthful appeared to have passed into the stomach, the patient was removed to a neighboring house. The pulse was very feeble and vacillating, from 40 to 48; the respiration was oppressed and labored; the surface was cold. Over the left eyelid there was slight ecchymosis. The pupil of that eye was slightly dilated, the right pupil was contracted; both were irresponsive to light. Sinapisms were applied to the surface. A few drops of brandy and water placed into the fauces were not swallowed, and the attempt to administer internal stimulants was not insisted on. It was observed that when blood and cerebral matter oozed unimpededly from the wound, the condition of the pulse and respiration improved. The Surgeon-General accordingly kept the external wound open by means of a silver probe, until a Nelaton's probe being brought, he made an exploration of the course of the ball. A splinter obstructed the track at the depth of about two and a half inches. An inch and a half further on, the bulb came in contact with a foreign body, which proved to be the disk from the occipital forced out by the ball; passing beyond this, the ball was detected, at a distance of over six inches from the entrance wound. Drs. Stone and Crane, having also distinctly felt the ball at this depth in contact with the bulb of the probe, it was decided that no attempt should be made to remove it or the foreign bodies, further than to keep the opening free from coagula, which, when allowed to form and remain for a very short time, would produce signs of increased compression, the breathing becoming profoundly stertorous and intermittent, and the pulse more feeble and irregular. Notwithstanding the free oozing from the external orifice, there was evidently much internal bleeding going on, as was indicated by the excessive extravasation into the orbits, accompanied by great ecchymosis of the eyelids. The protracted death struggle ceased at twenty minutes past seven o'clock on the morning of April 15, 1865. The eyelids and surrounding parts of the face were greatly ecchymosed, and the eyes somewhat protuberant from effusion of blood into the orbits."

At the autopsy it was found there was a pistol-shot wound of the head, around which the scalp was greatly thickened by hemorrhage into its tissues. The ball entered through the occipital bone about an inch to the left of the median line and just above the left lateral sinus, which it opened. It then penetrated the dura mater, passed through the left posterior lobe of the cerebrum, entered the left lateral ventricle, and lodged in the white matter of the cerebrum just above the anterior portion of the left corpus striatum, where

\* The table contains no cases later than 1890.

it was found. The wound in the occipital bone was quite smooth, circular in shape, with bevelled edges, the opening through the internal table being larger than that through the external table. The track of the ball was full of clotted blood and contained several little fragments of bone, with a small piece of the ball near its external orifice. The brain around the track was pulsatous and livid from capillary hæmorrhage into its substance. The ventricles of the brain were full of clotted blood. A thick clot beneath the dura mater coated the right cerebral lobe. There was a smaller clot under the dura mater of the left side. But little blood was found at the base of the brain. Both the orbital plates of the frontal bone were fractured, and the fragments pushed up towards the brain. The dura mater over these fractures were uninjured. The orbits were gorged with blood.

There is certainly no possible criticism of the treatment in this noted case; but, as a matter of scientific investigation, it may be queried whether, if the shock in this instance had not been so profound, active surgical intervention for the removal of the fragment would have been advisable or not, and, if not, what advantage was gained by the use of a probe?

In a large number of instances the surgeon has to meet such cases where the patients are not moribund, and may well consider the following questions: Whether active interference, involving the use of the trephine, is demanded as a rule in severe cases of this class; whether the removal of the bullet or of fragments should be attempted in penetrating wounds of the skull; whether to probe without the use of the trephine is advisable?

In order to add to the statistics on the subject, the accompanying table has been prepared by Dr. Herbert Smith, of Boston:

An analysis of these cases is worthy of attention. Ninety-one cases of penetrating pistol-shot wounds of the brain have been collected. Of these, 22 were found in the records of the Boston City Hospital, all the cases that entered during the last twelve years being taken according to date of entry. The remaining 69 cases were found recorded in current literature, most of them within the last fifteen years.<sup>2</sup> None of the cases antedated the period during which modern antiseptic treatment, in some form or other, has been employed, and no case has been included unless the bullet had penetrated the skull, or at least rested on the dura mater. As was to be expected, the percentage of recoveries in the hospital cases has been considerably smaller than in those extracted from the journals, since it may be presumed that the majority of the latter class had some special features, oftentimes an unexpected recovery, which seemed to warrant their being put on record.

Of the 22 City Hospital cases, five recovered, and 17 died, a percentage of recoveries of 22.7; of the whole 91 cases, 40 recovered and 51 died, a recovery percentage of 43.9. It is probable, therefore, that the ratios given in the following computations will in each case seem to show a better result than would be true of the whole number of such injuries, were it possible to collect them. The present investigation, however, is made for the purpose of obtaining *principles* for guidance in treatment; and the relative results of the various modes of procedure in the cases here recorded will hardly be affected by the absence of unreported

cases. Moreover, the loss will probably be in those cases which die within a few hours, from shock, and since it is in this class that little or no operative interference is ever possible, as a working basis for treatment the results in the cases here given can hardly be fallacious.

In classifying the injuries in relation to the part of the brain penetrated, it was found impossible, from the descriptions given, to make anything like a complete table of the portions of the brain traversed by the ball. The cases were therefore grouped according to the point of entry into the skull, thus giving the following table:

	Recovered.	Died.
Under chin . . . . .	0	1
Mouth . . . . .	2	0
Nose . . . . .	0	2
Orbit . . . . .	4	2
Eye-brow . . . . .	2	4
Forehead . . . . .	8	5
Temple . . . . .	9	16
Auditory meatus . . . . .	0	5
About ear . . . . .	7	7
Crown of head . . . . .	1	2
Parietal . . . . .	6	0
Occipital . . . . .	1	2
Not stated . . . . .	0	1
Total . . . . .	40	51
Hospital cases . . . . .	5	17

This may be summarized to show that, when the ball enters the skull at some point anterior to the plane passing through the external auditory meati, 25 have recovered and 34 died, out of 59 cases, a percentage of recoveries of 42.3. In 32 cases where the bullet entered in this vertical plane, or posterior to it, 15 recovered and 17 died, the percentage then being 40.6. If we except the five cases in which the ball entered directly into the auditory meatus, of which all died, the recoveries are 53.5% of the whole number. If we assume that those missiles which entered the anterior half of the skull injured the anterior portions of the brain, then these statistics will not bear out entirely the idea generally held, that lesions of the anterior lobes of the brain are less fatal than those of the posterior portions. Perhaps the greater fatality in these cases may be accounted for by the fact that in the majority the wounds were inflicted for suicidal purposes, the pistol being held close to the skull, where the bone is thinnest, and that therefore the direct injury to the brain is greater in the first series of cases than in the second. Again, most suicidal attempts are done in seclusion, and there is a considerable interval of delay before treatment is applied, so that the danger from shock is far greater, proportionally, than in gun-shot wounds received in battle, for example, since there all classes of wounds would be subject to a proportionate delay. This may explain the difference between the statistics of civil and military surgery. It is to be noted that next to the auditory meatus the most dangerous point of entry was in the temple, where, out of 25 cases 16, or 64%, were fatal.

Another series of tables (see page 402) illustrates the fatality of those cases where the bullet remained in the cranial cavity, as compared with that of the instances where the bullet perforated or was removed.

From these tables it will be seen that the mortality in the latter class is but 33.3%, while in the former it is 54%. Out of the five cases where the bullet perforated by its own momentum there were two deaths, while in six cases where the bullet was extracted by the trephine there were no deaths; and in

<sup>2</sup> The table contains no cases later than 1890.

five other cases, where the bullet had passed through the bone, but had not perforated the soft parts beyond, requiring an incision before it was dislodged, there were three deaths. These results are what would be expected, since, generally speaking, those bullets are removed by means of the trephine which have passed but a little way into the brain, the damage to the cerebral substance being slight, and the ease and thoroughness of drainage far greater. Though the numbers are too few to warrant conclusions as to operating, yet it is very significant that 100% of the cases of removal of the bullet by the trephine were successful, while 50% of those where the bullet passed completely through the brain proved fatal. We may yet, perhaps, come to believe that the damage which the careful surgeon will do in attempts to extract a ball which has penetrated the cerebral tissues will not be greater than the injury already done by the missile. If this should prove to be the truth, very decided views may properly be taken as to the advisability of thorough search for the ball in every instance.

BULLETS LODGED.		Recor'd.	Died.
Chin . . . . .	.	0	1
Mouth . . . . .	.	2	0
Nose . . . . .	.	0	2
Orbit . . . . .	.	1	0
Brow . . . . .	.	3	3
Forehead . . . . .	.	10	7
Temple . . . . .	.	5	14
Meatus . . . . .	.	0	5
About ear . . . . .	.	6	4
Parietal . . . . .	.	3	0
Crown . . . . .	.	0	2
Occipital . . . . .	.	1	2
Total . . . . .	.	34	40
BULLETS OUT.		Recor'd.	Died.
Perforated . . . . .	.	3	2
By trephine . . . . .	.	6	0
Incision . . . . .	.	2	3
Total . . . . .	.	10	5

Analyzing the cases where the ball remained in the cavity of the skull with reference to the point of entry, we find that 51, or 63% penetrated at a point anterior to the vertical plane passing the auditory meati, and of these 47% recovered, while 23, or 31% entered posterior to the same plane, in whom 10, or 43% recovered.

The following table was compiled for the purpose of showing the results of the various forms of treatment. Many of the records were incomplete in this respect, and it is probable that many more of the cases were at least probed than the table shows, though the records of trephining are probably quite correct, as so formal an operation would hardly be omitted in the account.

	Recor'd.	Died.
Trephined, ball removed . . . . .	5	1
Trephined, fragments removed . . . . .	1	2
Trephined, ball not removed . . . . .	1	3
Fragments removed . . . . .	3	5
Incision . . . . .	2	1
Incision, ball removed . . . . .	5	4
Probed . . . . .	12	13
Nothing recorded . . . . .	8	21
Trephined secondarily . . . . .	3	0
Died under operation . . . . .	0	1
Total . . . . .	40	51
SUMMARY.		
Ball removed . . . . .	10	5
Operation, ball not removed . . . . .	10	12
Probed only . . . . .	12	13
Nothing recorded . . . . .	8	21
	10	51

It would seem to show that operative interference, whether resulting in successful extraction of the missile or not, is not in itself so serious as some writers have supposed. Five out of six cases where the bullet was removed by the trephine, recovered. Out of 15 cases where the bullet was removed by various operations 10, or 66% recovered. In 37 instances of operative interference 20, or 54% recovered. Of 25 cases where the expectant plan was followed, except that the probe was passed, only 12, or 48% recovered, while in the remaining 29 cases, in which no record is made on the point under discussion, only eight, or 27.5% got well. To be classed among the latter cases, however, were those who were moribund when first seen, and where no treatment would have availed.

Turning to those cases where the bullet remained in the brain substance, the following table shows the mortality after various forms of treatment:

	Recor'd.	Died.
Trephined . . . . .	6	2
Fragments removed . . . . .	3	8
Probed . . . . .	12	10
Nothing recorded . . . . .	13	20
Total . . . . .	34	40

Here again the operation of trephining has shown better results than simple expectancy. Six cases out of eight that were trephined, that is, 75% recovered. Of 11 cases where fragments were removed all but three died, while in the 55 cases that were either probed, or in which no mention is made of treatment, there were 25 recoveries and 30 deaths, showing that, taking all the cases into consideration, the results with operation, and without operation, where the bullet remains lodged in the brain, are not markedly different.

Of very considerable interest is the large proportion of cases, 34 out of 91, or 37.4%, who lived for a longer or shorter time, carrying about with them a bullet in the brain. The following table was made to show what proportion of these cases suffered afterward with symptoms referable to the bullet:

LATER SYMPTOMS OF BULLET IN BRAIN.		<i>Recor'd.</i>	<i>Died.</i>
Dizziness . . . . .	1	0	
Epilepsy . . . . .	2	2	
Pain . . . . .	1	0	
Stiff and weak . . . . .	3	0	
Meningitis . . . . .	0	3	
Softening from fragments . . . . .	0	4	
Total . . . . .	7	9	

It is to be noted that many of these cases, that is, where bullets had lodged, were regarded as well within a few months after the injury, because up to that time no symptoms had supervened, so that the proportion of 16 out of 34 cannot properly represent the likelihood of after symptoms in these cases. In fact, in every case where the patient has been followed for several years after the accident there were noted more or less intense cerebral symptoms, and probably if the ultimate history of all these cases could be known, many more than the table shows would be found to have died from the injury done by the foreign body.

Of the 16 cases which were noted as having later symptoms, nine, or 56.2% died. If from the 34 cases of recovery with bullets in the skull we subtract the 16 who afterward had symptoms, there remain but 18, or 27% of the whole number injured who recovered without recorded symptoms.

The relatively large number of patients who are reported as having died later on from injury done by

fragments of bone imbedded in the brain, naturally raised the query as to how often such fragments were found and removed at operations, or were discovered later at the autopsy.

Out of 30 cases where record is made, in 15, or 50%, it is recorded that fragments of bone were found in the brain substance. In 10 cases the final unfavorable issue seems to be wholly or in part due to the presence of these spiculas of bone. In some of these cases the bits of bone were small and were in close apposition to the projectile when found; but in several instances there were large irregular fragments, splintered from the inner table, which had been carried a greater or less distance and various directions into the cerebral substance. This fact emphasizes the view that in all gun-shot wounds of the brain the problem is not a simple one of a single projectile of known size, but it must be remembered that there may be multiple projectiles, of jagged outlines, driven in various directions, causing laceration and pressure. In this connection, also, may be mentioned the fact that other foreign bodies, such as hair, bits of clothing, etc., may be carried in as well: under such circumstances it is hardly to be hoped that the wound is in an aseptic condition.

**Cause of Death.**—In not all of the 51 cases could the absolute cause be obtained. The following is approximately correct, and will serve as a working basis:

Shock	15	29.4%
Meningitis	9	17.6
Exhaustion	8	15.6
Abscess	8	15.6
Hæmorrhage	8	15.6
Œdema of lung	1	1.9
Septicæmia	2	3.9

Roughly speaking, 30% died within a few hours from shock; 18% died from meningitis; 16% from hæmorrhage; 16% later from cerebral softening or breaking down of bruised tissue; while the remaining 20% sank and died from the constitutional effects or from exhaustion. Of these causes of death the most frequent, namely, shock, can be but imperfectly controlled. The other classes are more under the control of surgery, and it is in these directions that we must look for future advances in this branch of cerebral surgery. The prevention of hæmorrhage by early operation, and of meningitis, abscess and death from exhaustion by the timely removal of foreign bodies and septic material will do much to better our present statistics.

With a view of determining the cause of death after the various methods of treatment, the following table was prepared:

	Shock.	Hæmorrhage.	Abscess.	Exhaustion.	Meningitis.	Septicæmia.	Œdema of lung.	Total.
Trophine and ball,	0	0	0	0	0	0	0	0
Incision and ball,	1	0	1	0	0	0	0	2
Incision late,	0	0	1	0	1	0	0	2
Probe,	1	3	5	2	2	0	0	13
Operation, no ball,	2	3	8	3	1	0	1	18
Nothing recorded,	8	7	1	2	5	1	0	24
	12	13	16	7	9	1	1	59*

\* This table includes cases who died later, after apparent recovery.

It will be seen that hæmorrhage caused death in ten cases where no operation was performed, and in but three cases where an attempt was made to extract the bullet. The deaths from meningitis give a similar showing, seven cases resulting fatally when no operation was performed, and but two when a preliminary operation was attempted. On the other hand cases of cerebral softening were met with eight times after operation when the missile was not extracted, but five times after probing, and but once when no operation was performed. This is perhaps explained by the fact that these cases were the protracted ones, giving time for late consideration and operative attempt.

The following table shows roughly the duration of life after injury in the various parts of the skull:

Duration of Life after Injury.	Face.	Forehead.	Temple.	Parietal.	Crown.	Occiput.	Total.
Few hours,	1	4	8	3	2	1	19
Few days,	0	7	6	7	0	0	20
Weeks,	1	5	2	3	0	0	11
Years,	0	4	0	0	0	0	4
Not given,	0	0	0	1	0	1	2
	2	20	16	14	2	2	56

It is to be noted that in the case of wounds in the temporal region, on the crown of the head and on the occiput, the larger number died of shock. The secondary results, namely, meningitis, cerebral abscess and exhaustion from constant suppuration, are most often found when the injury has been in the forehead or about the ear.

From a study of the preceding cases the following statements have been formulated:

Penetrating gun-shot injuries of the head differ from penetrating wounds of the other cavities of the body in that it is known that the foreign body has done damage to the contents of the cavity.

The consideration of these cases is not a simple problem of the localization of a single body, because not only may the projectile be split up into a number of fragments, but there are very likely to be larger or smaller fragments of bone carried in with it.

The bullet which plows its way through the soft cerebral substance always makes a track much larger than itself, necessarily bruising the surrounding brain substance a great deal. If this broken-down tissue becomes septic, the injury needs an unusually free opening for drainage, owing to the density of the surrounding wall, and the comparative softness of the contents.

If fragments of bone are not carried into the brain tissue, and if the disorganized brain substance does not become infected, and if cicatrization or encapsulation of the bullet does take place, it is to be considered a piece of good fortune, and not due to efficacy of treatment.

Even if the bullet lodges safely in the brain, and recovery appears to have taken place, a goodly number of these patients may be expected to have more or less disabling symptoms afterward, and a considerable proportion of them succumb ultimately to the missile which they carry.

A certain number of cases must necessarily die of primary shock. Many die of hæmorrhage, but hæmorrhage is best treated when its source can be reached.

Operations for the removal of projectiles, as far as can be determined by statistics, do not seem in themselves to be especially dangerous. It is likely that the injury already done to the cerebral tissues will not be added to by the manipulations of any competent surgeon, even if he be very thorough in his search for the missile; and this is particularly true from the fact that the surgeon has still a fear of manipulating inside the cranial cavity, and violence is rarely used.

The Nelaton probe, or one of similar construction should be dropped into the canal. The telephone probe has occasionally located the ball, but has many times failed. If a hard substance is felt the latter probe will determine whether or not it is metal.

In pistol-shot wounds of the skull the dangers are not the same as in similar wounds in the abdominal cavity. In the latter there is danger of immediate death from hæmorrhage, and also from the injury caused by faecal extravasation. In the cranial cavity the chief cause of death is the irremediable one, shock; and although septic inflammation is of almost equal importance, there is certainly nothing comparable to the danger from faecal extravasation that is to be dreaded in abdominal wounds. Furthermore, the danger of death from hæmorrhage is not an imminent one, as, owing to the nature of the contents of the cranial cavity, and also to the unyielding character of its walls, hæmorrhage is held within the fatal limit by the resistance of skull. There is, however, a danger, which is peculiar to the cranial cavity; namely, that the increasing pressure of the hæmorrhage taking place within the unyielding walls of the skull, may increase the shock, cause death or degeneration of nerve substances, with the resulting impairment of mental condition. Under these circumstances it may be said that a delay of a few hours is not of as great injury in cases of injury to the skull as of injuries to the abdominal cavities; but that treatment should be undertaken without unusual loss of time, yet its urgency is not as paramount as in cases of the abdominal injuries.

On referring to the table it will be seen that of 51 cases, 15 deaths occurred from shock; while in 19 cases death followed some suppurative process; and in eight there was death from hæmorrhage. Death from hæmorrhage can be prevented, if the diagnosis is certain, and time is given, by ligation of the carotid or of the meningeal arteries in a small number of cases. In the majority of cases, however, this operative treatment will be of little avail. It is, however, fair to suppose, that in the suppurative cases, a certain number can be saved by thorough aseptic and antiseptic irrigation, and careful surgical treatment in the way of promotion of asepsis and of drainage.

The following generalization seems justified:

It should be considered as a surgical rule, where the patient was not moribund, that the scalp should be dissected up, the wound thoroughly exposed; as a rule, the trephine should be applied. This will provide for thorough examination, and for drainage, as well as for a thorough exploration of the injury of the inside of the cranial cavity, and for the removal of splinters.

The treatment of the dura will require the exercise of some judgment. The wound of the dura is usually smaller than the calibre of the bullet. This wound

occasionally becomes clogged with clotted blood, and the proper egress of fluid is not granted. There may be an accumulation of blood behind it and of clot, which will prevent proper drainage, and cause abnormal pressure upon the cerebral substance. If this is the case, or if there is probability of this being the case, the wound in the dura should be enlarged to allow the escape of clot.

The use of the probe without a free dissection of the scalp is not likely to give much information of value. The introduction of a Nelaton probe carefully, after trephining into the pistol-shot wound of the cerebellar substance, is not attended with danger; a soft catheter can also be employed. Irrigation, by a gentle current of aseptic fluid, is also non-injurious, and may be of advantage in cleansing a cavity. The introduction of a large instrument or of the fingers will depend upon the size of the wound. The danger of such introduction, if done with skill, is not great; but the possibility of successfully removing the bullet hid in the cerebral substance is slight. It is desirable to localize the bullet as far as possible, but the means for doing so successfully are as yet imperfect.

Where the bullet can be traced directly to the opposite side of the skull, the counter-trephining should be done at that point; not necessarily with the expectation of finding the missile, since the angle of rebound is very variable and cannot be calculated, but in order to give better drainage, and to determine the presence of a fracture on the opposite side of the skull. The introduction of drainage-tubes into disorganized cerebral substance is perfectly justifiable, and has been used to advantage; in fact, there are cases where tubes have been passed completely through with excellent results.

In short, it may be said that the treatment of pistol-shot wounds of the skull should be conducted on the same principles as the treatment of perforating fractures of the skull by a sharp instrument. That is, the wound should be thoroughly explored and thoroughly cleaned; all loose fragments should be removed, including the bullet, if readily accessible. Drainage and strict asepsis are essential.

## Clinical Department.

### GYNECOLOGICAL CASES AT THE ST. ELIZABETH'S HOSPITAL.

SERVICE OF F. W. JOHNSON, M.D.

REPORTED BY DR. E. H. ROSS, House-Officer.

(Continued from No. 15, page 373.)

#### ELEVEN ALEXANDER-ADAMS OPERATIONS.

##### CASE I. Dilatation of the cervix.

N. W., single, twenty-three years of age, entered the Out-patient Department July 15, 1890, with the following history. Pain in the left ovarian region, running down the left thigh. Backache for one year. Slight leucorrhœa. Micturition at times painful. Bearing and dragging down feeling on standing. Menstruation began at fifteen; unwell every two months; flows two weeks; confined to bed first day.

Entered the hospital September 30th. Dr. Kingman used the packing faithfully to overcome the retroflexion until December 1st, when the same treatment

was continued by Dr. Johnson. No headway being made, the patient was examined under ether, and the uterus, with the prolapsed left ovary and tube, were found firmly fastened backwards towards the left, by adhesions. Dilatation of the cervix to secure drainage, breaking up of adhesions, and fastening the uterus forward by shortening the round ligaments, was advised.

December 22d. Operation. Dr. Conant assisted. The cervix was well dilated, and an Alexander-Adams operation done.

January 29th. Discharged. Uterus in excellent position.

#### CASE II. Straightening uterine canal.

B. C., single, forty years of age, entered the hospital November 25th. Menstruates regularly every four weeks. Flows four to five days. Pelvic pain just before and during menstruation. Frequent backache. Unable to work.

December 5th. Examination under ether showed cervix and body of uterus undeveloped; anteversion of body and neck, with retroversion. Advised straightening the canal and an Alexander-Adams operation.

December 29th. Cervix and body straightened, canal dilated, and the round ligaments shortened. It was necessary to use the catheter for ten days.

January 13th. Discharged. Anteversion overcome, and uterus in perfect position.

#### CASE III. Emmet's operation on the cervix.

J. C., single, twenty-five years of age, entered the hospital December 2d. She complained of constant backache and sagging down. Phtisical family history. Diagnosis: Bilateral laceration of the cervix with ectropion and retroversion. Patient had been wearing a pessary for about a year, and although it corrected the retroversion and relieved the backache and sagging down, she was anxious to get rid of it, and asked for an Alexander operation.

December 5th. Operation on the cervix and shortening of the round ligaments. Dr. Conant assisted. Small abscesses formed on both sides where the cut was made for the Alexander.

January 25th. Discharged. Uterus in perfect position. Operation on cervix a success.

#### CASE IV. Uterus curetted. Emmet's operation on the cervix.

F. B., widow, twenty-eight years of age, entered the hospital December 8th. Has had two children. Last one born five years ago. First delivery was instrumental, and second was a breech presentation. Perineum was ruptured at the first confinement, and the cervix was lacerated at the second. Menstruates regularly every four weeks; flows one week; saturates fifteen to sixteen napkins; severe pain in ovarian regions and thighs during menstruation. Frequent sick headaches. Constipation, painful, and, at times, bloody defecation. Dragging in back and groins. Diagnosis: Ruptured perineum, bilateral laceration of cervix with erosion, chronic endometritis with mucopurulent discharge and retroflexion.

January 9th. The uterus having been got into proper position by packing, the cervix was operated on, the uterus which contained considerable hyperplastic tissue was thoroughly curetted, and the round ligaments were shortened.

Convalescence was without a drawback, and she was discharged February 1st. The uterus was in perfect position and the operation on the cervix was a success.

March 14th. Evidences of a return of the hyperplastic condition of the endometrium being present, she was advised to enter the hospital for a second curetting.

#### CASE V. Uterus curetted. Emmet's operation on the cervix.

F. B., widow, thirty-four years of age, entered the hospital December 8th. Phtisical family history. Has had five children. For five years has menstruated every three weeks; flows four to seven days; saturates twelve to eighteen napkins. Severe dysmenorrhœa. Profuse leucorrhœa. Constipation. Severe backache. Pain in the rectum. Diagnosis: Bilateral laceration of the cervix, most extensive on the left, with erosion and enormous hypertrophy of both anterior and posterior lips. Retroflexion and chronic endometritis.

Packing having been successfully used for a month and a half, the cervix was operated on, the uterus, containing a small amount of hyperplastic tissue, was curetted, and the round ligaments shortened. The ligaments were found very friable, but were of good size when pulled up.

#### CASE VI. Uterus curetted.

F. D., single, twenty-three years of age, entered the hospital December 17th. Family history phtisical. Menstruation began at eleven; regular every four weeks; flows quite profusely four or five days. No pelvic pain, but severe headache during menstrual flow. Sagging and dragging down with burning in left ovarian region. Leucorrhœa for years, necessitating the constant use of a napkin. Diagnosis: Chronic endometritis, salpingitis on the left side, retroversion.

December 19th. Operation. Dr. Conant assisted. After thoroughly dilating the cervix for the purpose of drainage, the endometrium was curetted. Finally the round ligaments were shortened.

January 7th. Discharged. Uterus in normal position.

Reported the first of March. Entire relief of sagging and dragging down and burning feeling in left ovarian region. Scarcely any leucorrhœa.

#### CASE VII. Cervix dilated.

T. R., single, twenty-one years of age, entered the hospital January 8th. Menstruation began at fourteen; regular every four weeks; flows five to six days; uses twelve to fourteen napkins. Confined to bed first two days of the flow on account of severe pain in the back and lower abdomen. Considerable leucorrhœa. Bowels constipated. Diagnosis: Retroversion with adhesions, chronic endometritis.

January 20th. Operation. Dr. Conant assisted. Cervical canal dilated to secure free drainage for the endometritis, and then the round ligaments were shortened.

February 10th. Discharged. Uterus in perfect position. No return of dysmenorrhœa since the operation.

#### CASE VIII. Retroversion, with adhesions.

M. M. G., married, twenty-seven years of age, entered the hospital January 16th. Symptoms began eighteen months ago, soon after marriage. Complained of constant pain in small of back and left ovarian region. For one year, just midway between menstrual periods, has suffered from nausea and vomiting. Leucorrhœa since puberty. Menstruation began at sixteen; regular every four weeks; flows two days; uses nine napkins; severe pain in lower abdomen first two days of the flow. Never pregnant. Diagnosis: Chronic

endometritis, uterus retroverted and fastened by adhesions involving left ovary and tube.

January 21st. Operation. After thoroughly dilating the cervical canal to secure free drainage the adhesions were broken up, and the uterus secured in its proper place, forwards, by shortening the round ligaments. Dr. Conant assisted. Packing was firmly placed in the vagina after the operation and allowed to remain four days.

February 21st. Discharged. Uterus in excellent position.

CASE IX. Retroversion, with antelexion of cervix and body.

E. L., single, twenty-six years of age, entered the hospital January 19th. Phthisical family history. Has had several attacks of melancholia with delusions during the past few years. During one attack was sent away, but returned in a few months apparently perfectly well. Complained of sagging and dragging down in lower abdomen. Frequent headaches. Menstruation began at fourteen; regular every four weeks; flows three days; soaks six to seven napkins; sometimes severe pain during the first day of the flow. Diagnosis: Cervix small and conical, antelexion of neck and body with retroversion.

January 28th. Operation. Cervical canal dilated and the round ligament shortened. Dr. Conant assisted.

February 26th. Patient thinks devils come out of her mouth when she speaks. Thinks the other patients are laughing at and talking about her.

March 16th. Discharged. Uterus found in excellent position by Drs. Johnson and Conant.

CASE X. Retroversion, with adhesions. Both ovaries prolapsed.

A. C., single, twenty-five years of age, entered the hospital January 23d. She was sent in from the Out-patient Department by Dr. Conant. Phthisical family history. Had pneumonia ten years ago. Dates her pelvic troubles from a severe attack of dysentery which occurred five years ago. Not been able to work since that time. Complained of pain in left ovarian region and dragging in the back. Menstruation began at fourteen; unwell every six to seven weeks; flows four to eight days; flows but little. Confined to bed for three days on account of dysmenorrhoea. Constant leucorrhoea. Bowels constipated. At times painful micturition.

January 21th. Examined under ether by Drs. Johnson, Kingman, and Conant. Diagnosis: conical cervix, retroversion with adhesions, prolapse of both ovaries. Advised dilatation of cervical canal, breaking up of adhesions, and shortening the round ligaments.

February 11th. Operation, as advised January 24th. Dr. Conant assisted. On the left side the ligament was adherent, and it was necessary to open up the canal as far as the internal ring. The peritoneal cavity was opened, but was quickly closed with small catgut sutures. Convalescence was uninterrupted. Her stay in the hospital was prolonged by a non-inflammatory swelling of the left knee, leg and ankle, which appeared as soon as she began to get about. At first, pain was complained of in knee and ankle, but this soon subsided and left only the swelling. There was gradual improvement under the use of Fowler's solution, iodide of potassium, and cod liver oil. Uterus was well forward, but was drawn a little to the right of the median line.

CASE XI. Emmet's operation on the cervix.

K. C., married, twenty-six years of age, entered the hospital February 15th. Has had four children. First labor was instrumental. Five months ago had cervix and perineum operated on, but both operations were a failure. Menstruation began at seventeen; regular every four weeks; flows three days; uses three to four napkins; severe pain in lower abdomen during the first day of the flow. Has constant pain in the right groin with dragging and sagging down.

February 10th. Operation. Dr. Twombly, assisted by Dr. Breck, operated on the cervix; then Dr. Johnson, assisted by Dr. Twombly, shortened the round ligaments. Both operations were a perfect success, especially the one on the cervix. She was discharged, all symptoms having been relieved.

(To be continued.)

## Medical Progress.

### RECENT PROGRESS IN SURGERY.

BY H. L. BURRELL, M.D., AND H. W. CUSHING, M.D.

(Concluded from No. 15, page 377.)

#### SOME OF THE DANGERS OF IMMEDIATE SUTURING IN CERTAIN CASES OF FRACTURE OF THE PATELLA.

AFTER an experience of 13 cases of fracture of the patella treated by immediate suturing, Fowler has somewhat modified his views regarding the treatment of this injury.<sup>13</sup>

"In a number of cases he observed persistent and widespread suppurative which occurred primarily outside the joint. He explains this by the fact that in certain cases the upper recess of the joint cavity is ruptured. As a result there necessarily occurs an extravasation of the fluids effused on receipt of the injury and immediately afterward into the space between the vastus internus and the bone. The opening of the knee-joint in such cases is almost certain to produce suppurative, since it is impossible to reach this effusion by antiseptic lotions. Application of pressure would tend to further extension of the infection by forcing the effused fluids through the rent in the upper recess of the synovial sac, instead of permitting them to escape through the drainage-tubes placed in the joint.

"This view was confirmed by the observations of Riedel, who, through a death on the table during an attempt to suture a fractured patella as a primary operation, was enabled to make an immediate examination of the parts. This showed that there were two points of perforation of the upper recess of the joint, and that there was an extensive hemorrhage between the vastus medialis and the bone.

"Rupture of the upper recess of the knee-joint need not necessarily be attended by appreciable swelling of the thigh, nor are there any pathognomonic signs which would denote that this injury had taken place. If a very severe injury inflicted on the knee is followed by very slight distension of the joint-capsule, or if such swelling has taken place but has suddenly and causelessly disappeared, a suspicion as to the nature of the injury may be entertained.

<sup>13</sup> Brooklyn Medical Journal, vol. v, No. 3. American Journal of the Medical Sciences, vol. cl, No. 6, June, 1891, p. 625.

"If, on applying a tight bandage to the swollen knee, pain and distension are increased, this might be considered as a proof that the joint-cavity was still intact, and when this condition is present Fowler believes that the primary operation of suture may be resorted to without delay and with almost positive safety, except when in addition to the break in the patella there are extensive and severe contusions in the neighborhood of the joint. If a case is thus complicated the lessened vitality of the part renders its resistance to infection so slight as to constitute a very positive contra-indication to exposing the tissues to infection.

"Even though the operation is not advisable immediately after the injury, the surgeon need not reject entirely the idea of operation. After one or two weeks, when the inflammatory exudate has been absorbed, and the injured tissues have regained their vitality, the knife may be used with safety."

#### THE PATHOGENESIS OF POPLITEAL CYSTS.

Poirier, after post-mortem observations of over a thousand knee-joints, and after clinical observations on upward of a hundred patients suffering from cysts about the knee,<sup>14</sup> states that popliteal cysts, even those which occupy the portion of the bursa, are nearly always of articular origin. Of a hundred cases subjected to most rigid examination, not one was found which had not a distinct articular origin. The commonest and best-recognized popliteal cyst is that which is found external to the tendon of the semi-membranous in the popliteal flexure. It is very prominent when the leg is extended, but seems to disappear on flexion. It evidently involves the bursa placed between the tendon of this muscle and the internal condyle. This bursa is, however, in closer relation to the cavity of the joint than any of the other bursa, and often communicates with it directly. Another form of cyst, not so frequently recognized, is that due to the outgrowth of the synovia of the joint. It involves the bursa beneath the popliteus, and appears as a deep-seated swelling in the upper portion of the calf.

A third variety of popliteal cysts is that which appears in the upper portion of the condyloid region. The bursa placed above the internal condyle is usually a prolongation of the synovia of the joint. Finally, cysts may appear in any part of the joint presenting the features of ganglion but really due to the development of subsynovial cysts or to synovial hernia.

#### RESECTION OF THE SACRUM IN INTRA-PELVIC OPERATIONS.

This is becoming an interesting subject, and A. Broca<sup>15</sup> has contributed an interesting article upon the preliminary resection of the sacrum. These operations are of two kinds: in one the resection is final, the bone being removed; in the other, the resection is temporary, and the bone is restored after the operation. In the first operation, that of Kraskie, a longitudinal incision is made in the median line from the middle of the sacrum to the anus. The tissues are divided to the bone. The gluteal muscle and the sacro-sciatic ligaments are divided; and then with the chisel and mallet the lower left half of the sacrum is

removed as far up as the third sacral foramen. The canal is not opened if the division of the bone is made somewhat to the left of the median line. This, however, is not a matter of much importance.

The temporary resection, with an osteo-cutaneous flap, was proposed by Heinecke, for cancer of the rectum, and has been performed by Hégar for a gynecological operation. A Y-shaped incision is made over the sacrum, commencing an inch and a quarter below and within the posterior inferior spine of the ilium, and ending at the tip of the coccyx. The upper flap is left adherent to the posterior surface of the sacrum. The muscles and ligaments are separated from the bone, and the rectum is removed from the anterior surface. Then the sacrum is divided with a chain-saw along an oblique line, the right extremity of which is between the third and fourth sacral foramina, the left extremity at the sacral cornu. When the bone has been divided the flap with the skin is raised and replaced at the end of the operation.

MM. Lévy and Delbet have modified the form of the operation by making the bone-flap from the lower part of the sacrum cut transversely across. This has the advantage of preserving the insertions and the strength of the pelvic floor.

By resection of the sacrum free access is obtained to the pelvic contents. The operation is indicated in cancer of the rectum, for hysterectomy, and for some cases of pelvic abscess; especially those which are separated from the general peritoneal cavity, and are not accessible for extirpation.

The operative treatment of rectal cancer, with especial reference to Kraskie's sacral method, has been elaborately placed before the profession, with especial reference to all the operative detail and technique, by Paul Thorndike.<sup>16</sup>

#### THE PRESENT LIMITATIONS OF SPINAL SURGERY.

Abbe has contributed a valuable paper<sup>17</sup> on the subject of spinal surgery. He believes that the Morton injection for spina bifida should be no longer employed, but that the sac of this tumor should be excised by the method of Mayo Robson.

In spinal caries the operation should be undertaken when sinus drainage is exhausting the patient. Then the curetting may extend even to the bodies of the vertebrae. Tubercular sinuses should be cleansed with peroxide of hydrogen and iodoform injections. Cold abscesses should be treated at first by Bruns's method.

In paraplegia from fracture, operation should not be undertaken until the hemorrhage has been absorbed and the bones have united. A subjective sense of tingling and pain in the paralyzed and anesthetized limbs is an indication rather of irritation of a divided cord by the cicatrix or by bone spicula than of conduction along the cord. Observation of absence of tendon reflexes is the only satisfactory proof of probable transverse lesion. Involuntary twitching and jumping is a reflex action having its nervous origin in the distal part of the divided cord. It may exist years after the injury and must not be regarded as probably indicating ultimate recovery. Operation offers little hope in total transverse section.

Pain in the hyperesthetic part may be relieved by breaking up adhesions, nothing more can be expected.

<sup>14</sup> *Le Progrès Médical*, t. xlii, No. 43, 1891. *American Journal of the Medical Sciences*, vol. cv, No. 6, June, 1891, p. 629.

<sup>15</sup> *Gazette Heb. de Méd. et de Chir.*, No. 10, t. xxvii, p. 167. *Journal of American Medical Sciences*, April, 1891.

<sup>16</sup> *Boston Medical and Surgical Journal*, May 7, 1891.

<sup>17</sup> *Canadian Practitioner*, vol. xvi, No. 5. *American Journal of the Medical Sciences*, vol. cv, No. 6, June, 1891, p. 627.

Paresis and limited anæsthesia of the lumbar-root supplies call for operation. This will probably be followed by recovery. Paraplegia and persistent acute pain warrant a diagnosis of myelitis and local meningitis. For this condition a chance for relief should be given, as White's case shows the benefit which may follow operation under such circumstances.

#### THE TREATMENT OF ARTERIO-VENOUS ANEURISM.

The treatment of arterio-venous aneurisms has long been peculiarly interesting and difficult. B. Farquhar Curtis, M.D.,<sup>18</sup> has contributed an extremely valuable article, and relates two cases which were treated by excision of the arterio-venous aneurism. Besides this he has collated a large number of arterio-venous aneurisms which have been treated by different surgeons. He arrives at the following conclusions:

"We have seen that compression is only suitable for cases which are seen early, and in which the affected vessels lie superficially; and if it is not successful at once, or if its employment is difficult or painful, the risks of operation are not sufficiently great to warrant delay. It is my conviction that all these cases should be treated by operation, with the single exception of the cases involving the internal jugular, or requiring ligation of the common femoral artery and vein. It does not appear necessary to distinguish between aneurismal varix and varicose aneurism as to treatment. The choice of methods depends upon the size and situation of the aneurism. In a general way, it may be said that all small aneurisms not involving the larger vessels of a limb should be extirpated unless important nerves are jeopardized by the dissection, or, as on the face, it is important not to leave a scar. The treatment selected for larger aneurisms depends upon their situation. Those of the neck which involve the external jugular vein will rarely require treatment, but should it be necessary, such cases are best treated by double ligation of both vessels. In other situations the simple ligation of the vessels should not be chosen, for it will, in most cases, require as much dissection as will incision or extirpation, while not giving the same immunity from relapse. The surgeon should make an incision down upon the sac in its entire length, and attempt to dissect it from its bed. If this prove difficult or impossible because of inflammatory thickening or intimate connection with important parts, the sac should be incised, for it is often easier to secure the vessels when the sac is freely opened. The sac could then be left entirely in place, or it could be partly removed, and it may be as well to say that suture and simple drainage of the sac have been found sufficient, and that it is unnecessary to resort to packing. In closing, we must not forget that the recently-introduced suture of veins, and the successful experimental suture of arteries, may alter our methods of treatment in some of these cases; in fact, Bassini<sup>19</sup> has already cured a case by double ligation of the artery and suture of the opening in the vein."

A very complete literature of cases is appended.

#### BONE AND JOINT DISEASE, A SEQUEL OF CERTAIN SPECIFIC FEVERS, ESPECIALLY SMALL-POX.

The attention of the profession has been called from time to time to this subject by many writers, and

<sup>18</sup> American Journal of the Medical Sciences, vol. cl, No. 2, February, 1891.

<sup>19</sup> L'Éclair Méd., April 15, 1890, p. 16.

Earnest J. Neve, M.D.,<sup>20</sup> has contributed a valuable article on this subject, and comes to the following conclusions:

**Diagnosis.**—The history and period of onset of these diseases is characteristic. A bone or joint lesion occurring in an infant or young child three or four weeks after small-pox and running a subacute course with suppuration, leaves little doubt as to its nature. The patients are usually profoundly pock-marked with recent scars. Cases seen for the first time as late as two or three months after small-pox show from the advanced state of their lesions that the condition must have arisen soon after, if not during, convalescence.

**Treatment.**—In many cases the treatment required is extremely simple. Incision and drainage of subperiosteal collections is sufficient. Sequestra become separated with great rapidity [in spite of the otherwise subacute course of these diseases] and can be readily removed. In the joints simple incision and drainage are sometimes productive of good results, but they are more frequently followed by prolonged suppuration and final ankylosis. So the choice really lies between modified excision and arthrectomy. I think that the joint should be freely laid open and the synovial membrane removed as far as possible. The amount of articular cartilage removed must depend upon the extent of the disease. But generally the surgeon should aim at removing sufficient to diminish the risks of ankylosis and yet avoid interference with epiphyseal growth.

Owing to the age of the patients recovery is usually rapid. Indeed, even if left untreated, there is a strong tendency to natural cure, whether by spontaneous extrusion of sequestra or by suppuration and ankylosis of joints.

(a) *Periostitis, epiphysitis, necrosis, and arthritis* may occur after and on account of exanthematous fevers, especially small-pox.

(b) They usually, but not invariably, appear during late convalescence.

(c) In typhoid fever the most frequent of these sequels is periostitis. And this attacks long bones by preference, especially the tibia, but seldom results in necrosis. Arthritis, if it ever occurs, must be extremely rare.

(d) *Alveolar necrosis* is of not infrequent occurrence. It is a commoner sequel of scarlatina and measles than of the other exanthemata.

(e) *After small-pox:* (1) *Arthritis*, the most characteristic lesion, occurs with greatest frequency in the elbow, and less often in the knee, shoulder, hip, and wrist. Sometimes it is primary. Occasionally it is secondary to epiphysitis. (2) *Next in frequency* is partial or entire necrosis of long bones, especially the ulna. (3) *Suppurative epiphysitis* with or without necrosis is not uncommon. The acromion is frequently attacked, as are also the long bones. (4) These post-variolous diseases occur chiefly, if not entirely, in infants and young children, and are often multiple. They are subacute and a fatal termination is rare.

(f) The various conditions enumerated above have a tendency to spontaneous recovery by suppuration, extrusion of sequestra, and ankylosis of joints.

(g) As treatment, incision and drainage are, with removal of sequestra, usually sufficient. But in cases of arthritis, prolonged suppuration and ankylosis may

<sup>20</sup> American Journal of Medical Sciences, May, 1891, p. 469.

be avoided by arthrectomy or partial resection of the joint.

#### LOCATION OF FOREIGN BODIES BY ELECTRO-MAGNETISM.

Kummer located a sewing-needle imbedded in the right knee by means of a magnet.<sup>21</sup>

"A needle was driven into the knee by a blow. Eight days later the movements of the joints were painful, and synovitis developed. It was impossible by palpation to locate the foreign body. The knee was placed upon an electro-magnet charged with a current of about ten amperes; on carrying a galvanometer over the surface after removal of the magnet, a deviation was evident. By repeated searching with the galvanometer the position of the foreign body was accurately determined and the direction of its long axis also became apparent. The surface was marked with nitrate of silver and the following day the operation was performed. Incision was carried down to the capsule of the joint without finding the needle. On placing a galvanometer needle in the wound, such an action was manifest that the operator felt no hesitation in opening the joint. A considerable quantity of sanguinolent synovia escaped, and the needle was found in the upper angle of the incision, lying between the synovia and the fibrous capsule, and corresponding closely in position with that marked on the surface by the aid of the galvanometer."

Kocher had a patient in whom, after anomalous nervous symptoms, lasting many months, a needle was discovered by means of the galvanometer; and Dumont records a case in which a primary operation was unsuccessful in removing the foreign body; but a second operation, aided by the galvanometer, enabled the operator to reach the seat of trouble. In addition several cases are cited by Graeser, Lauenstein, and Kalin.

**THE HOLY COAT AT TREVES.**—Among the miracles announced as resulting from the exhibition of the Holy Coat at Treves are the curing of the withered arm of an abbé, the restoring of the sight of blind persons, and the curing of cripples. Each case is declared to be supported by medical testimony, but the details will not be published until the exhibition of the relic is finished.

## Reports of Societies.

### ASSOCIATION OF AMERICAN PHYSICIANS.

THE SIXTH ANNUAL MEETING, HELD IN WASHINGTON, SEPT. 22-25, 1891.

(Continued from No. 15, page 384.)

WEDNESDAY. — SECOND DAY.

#### THE REMOTE RESULTS OF THE REMOVAL OF THE OVARIES AND TUBES.

DR. WILLIAM T. LUSK, Referee, of New York, opened the discussion on this subject:

It must be admitted, in fairness, that the removal of diseased ovaries and tubes is followed in many cases by the relief of local pain; that the removal of pus collections, whether in the tubes or ovaries, eliminates a source of danger to life; that when properly performed the dangers of the operation, *quoad vitam*, are small, not to be weighed for a moment against the terrors of chronic invalidism.

What is the usual later history of cases of double oöphorectomy, where the operation has been skillfully performed, and the recovery from the same has been speedy and complete? The central event is the cessation of the menses. By calling this the central event I mean to indicate that the woman has lost, in the disappearance of the menses, the most distinctive sign of sexual activity. At the same time, the uterus diminishes in size, the vagina becomes narrow and shrunken and its transverse ridges are effaced. In many instances the vaso-motor disturbances, such as the hot flashes, and profuse perspirations serve as efficient reminders that the climacteric due at fifty has been reached, let us say, at twenty-six.

The result of removal of healthy organs for a variety of nervous derangements, as was to have been expected, has proved a failure. In a few instances, contrary to my better judgment, I have operated in accordance with this indication, but I have never seen the slightest benefit accrue. The same wearisome experience has fallen to the lot of many of my colleagues. I am therefore tempted to assert that the performance of normal ovariectomy for epilepsy and insanity is to be regarded as hardly better than malpractice.

The extent and frequency of serious mental changes as a consequence of the removal of the uterine appendages is a question which calls for very careful investigation. One of my patients operated upon five years ago is now insane. I know nothing of her family history, but can state that she was not "queer" at the time of the operation. The recovery from the latter was uncomplicated and she left the hospital "cured." There is no trace now of pelvic trouble, but the pains have returned, and she now sits all day brooding upon the change that has taken place as regards her physical state. The reports of operations as to the connection of castration with mental changes differ widely. Some deny any connection between the two events, while Glaevecke noted melancholia in eleven out of thirty-three patients. In the table furnished by Dr. C. C. Lee, which was compiled from carefully-kept records, it is seen that depression is noted in nine cases out of twenty-six. In one instance, at the end of a year, and in three at the end of two years, the patients recovered their wonted spirits. Two of the unimproved patients were epileptic. Dr. Lee's report does not tell a very encouraging story.

<sup>21</sup> *Revue Méd. de la Suisse Romande*, No. 10, 1890; *American Journal of the Medical Sciences*, vol. ci, No. 6, June, 1891, p. 628.

A review of the results of Mr. Tait's operation shows that as a rule the change of life is effected without unusual disturbances, without loss of womanly graces, and that the sexual appetite in many cases persists. On the other hand, in certain cases, fistulae, hernia, adhesions, local inflammations, and a variety of physical changes complicate the issue. In some instances the relief is immediate, in many it is long delayed; in a few it never comes at all.

The more the question is studied, the more clear it becomes that the loss of her ovaries does make a difference to a woman. It is time to echo in this country Dolérís's cry in France: "Too many useless mutilations; not enough conservative gynecology."

There will always be a field for the beneficial employment of Mr. Tait's operation, but its author never intended it as a panacea for every feminine ailment.

At the risk of having the finger of scorn pointed at me, I do not hesitate to confess that in cases of enlarged and tender tubes I re-sort to rest, the vaginal tampon, donches, massage, faradism and a tonic regimen. If the tubal swelling is intermittent, and is associated with a narrow cervical canal, I am not afraid to use Goodell's dilator to secure free drainage of the uterine cavity. If the damming up of secretions in the tubes is the result of adhesions, I try to break them up by combined manipulations, according to Schultz's method, provided the tubes do not contain pus. If I am in doubt, as regards this point, I employ an exploring needle passed upward through the vagina. I am in accord with Landau, Munde, Grandid and others, who maintain that one can often effect a cure by the withdrawal of the fluid through the vagina, and in a pyosalpinx which is near the vagina, I do not hesitate to open and drain from below. If, owing to the presence of a pus-tube, or of well defined ovarian disease, or where owing to uncertainty of diagnosis or failure of treatment, it is decided to open the abdomen, it will be well in future to consider the recommendations of Martin and of Polk, not in all cases to remove the entire organs, but to study in each case with care, whether by removing simply the portion affected with disease it may not be possible at the same time to relieve pain, and preserve the feminine function.

It cannot be too often repeated that the successful removal of an organ is not a triumph of art, but a confession of defeat.

DR. WHARTON SINKLER, Co-referee, of Philadelphia, spoke as follows:

In considering the results of the removal of the uterine appendages, two questions are to be considered: first, if the removal of the ovaries was resorted to for disease of these organs; and, secondly, if the operation was done for disorders of the nervous system which were aggravated at the menstrual period, and which it was hoped could be cured by causing cessation of menstruation.

I have known many most satisfactory results to follow the removal of the ovaries and tubes for pyosalpinxitis, ovaritis, and other inflammatory conditions of the reproductive organs; and the general testimony is, that it is in these conditions that the operation is followed by the best permanent results.

The physiological effects appear to be the same, whether the organs removed have been diseased or healthy. The age at which the operation was done has some bearing on the symptoms which follow. Young subjects present more marked phenomena than

older persons. When the uterine appendages have been removed before puberty, or near the beginning of the menstrual function, the development of sexual characteristics is arrested. If, however, these organs are removed after full womanhood, no change takes place in the peculiar feminine characteristics. These are universally admitted facts. The phenomena which follow the removal of the ovaries, as Tait expresses it, "match in all other respects the process of the climacteric change." This is about the gist of the matter, We find in almost all cases as soon as the patient has recovered surgically, that the various symptoms belonging to the change of life are present. The most prominent of these are the flushings and sweats so commonly seen at the menopause. These occur most frequently during the first few months after the operation, sometimes annoying the patient intensely. These symptoms reach a climax in from three to six months, gradually disappearing in a year, or a year and a half.

Disturbances of the heart's action are common, and rapid pulse (tachycardia) is a not infrequent symptom.

There is a wide-spread impression that women upon whom this operation has been done gain in flesh rapidly, and become coarse and masculine in appearance. This is entirely erroneous. It has never been my experience to see, or hear of, a woman who has become unfeminine in the contour of the bust or limbs in consequence of removal of the ovaries.

The growth of hair on the lip and chin does not occur any more frequently than it does in women whose ovaries have never been tampered with.

Patients often suffer from various nervous troubles after removal of the uterine appendages; they are often restless and irritable, or depressed mentally. In some cases there is merely mental depression or mild melancholia; in others, there is either acute mania immediately following the operation, or a mild form of insanity gradually deepens and becomes a chronic mania. It is only fair to call attention to the fact that acute mania may follow other surgical operations. The number of cases following oophorectomy is large. Dr. T. Gaillard Thomas has reported six cases of mental disturbance following gynecological operations. Mairer has collected twenty-five cases of insanity following operations from his personal experience. Dr. William Goodell states that two of his patients became insane a few months after the operation. Dr. Graeme M. Hammond reports a case of acute insanity following ovariectomy in four or five days. Dr. E. E. Montgomery records two cases, out of twenty-five to thirty, who became insane after the operation. I have under my own observation several cases of insanity after removal of the ovaries.

The consensus of opinion respecting the sexual appetite after castration in women, is that it is but little affected. The effects of the removal of the ovaries upon sexual appetite proves what has long been believed to be the case; namely, that the sexual desire does not depend upon the ovaries but upon the centres in the spinal cord. I have seen two cases in which onanism persisted after the operation the same as before.

As to the benefit derived by patients who have undergone oophorectomy for insanity, epilepsy, hysteria, and the different forms of neuralgia and nerve troubles, there are a large number of cases who do make a good recovery after the removal of the offending organs. In cases of extreme dysmenorrhea this is con-

spicuously true. On the other hand, a vast number of patients, who are temporarily relieved by the operation, in a few months are in as bad a condition as ever.

DR. S. WEIR MITCHELL had seen many cases of ovariectomy where the ovaries ought never to have been touched. Judging from his experience of the past, he feared that among the most reckless operators will be the women operators of the future. He thought that greater thoughtfulness and more general medical conscience was needed in this matter. Every new medicine and every new operation is apt to induce excesses either in medicine or surgery. After a while these cure themselves, often after heavy cost. As an example of this, the introduction of the bromides was recalled. These ovarian cases have not gone on long enough to give really remote histories. We want to know what becomes of women, operated on at eighteen to twenty, ten or fifteen years afterwards. The histories of such cases as thigh amputations ten or fifteen years later, show remarkable changes in the nervous systems of the patients. In a long professional experience, he had only in fifteen cases been forced to call upon the surgeon for removal of the ovaries. The practical abolition of the death penalty in surgery has produced an amount of temptation in the surgical mind which is responsible for a good deal of the mischief under consideration, and has made men too ready to operate without medical consultations. This operation should never be done by a surgeon without consultation with a physician. Dr. Mitchell related four cases, all young married women, and all from California, who had been condemned at home to lose their ovaries. In one case Dr. Goodell believed that no other cure was possible. Under Dr. Mitchell's care they were all cured. All are happy women to-day, and it is three years since the last one was cured. All have had children since, and are able to do everything that a woman should do. Had their ovaries been removed they would have doubtless gotten well, and have had reasonably happy lives; if preferred to get them well without crippling them in any way.

DR. JAMES J. PUTNAM reported that he had sent a circular to most of the gynecologists and surgeons in Boston, in order to report their experience and opinions in so far as they had not hitherto been published. The great majority of them had answered that they had not used oöphorectomy in the treatment of nervous symptoms. Twenty-four hitherto unpublished cases had, however, been given by Drs. F. W. Johnson (11), John Homaus (8), J. W. Elliot (5).

Eight of these had apparently been benefited by the operation, the good result not appearing sometimes for a number of months. In one case the patient did not improve for three years, and for that reason this case was not included among those reported as benefited. The remaining cases had not been benefited. In several cases maniacal symptoms had followed the operation, but these symptoms had only been of temporary duration, except in two or three cases where it was subsequently found there had been previous indications of insanity. Dr. A. T. Cabot was also referred to as having had two cases of ovariectomy in which serious mental disorder had followed, which in one case lasted for many months.

In summing up and stating his own opinion, which he believed to be also that of the surgeons quoted, Dr. Putnam said that the recent advances in our knowl-

edge of neurasthenia and its treatment, had made most of the neurologists distrustful of those modes of treatment which were not based upon a recognition of the fact that serious nervous symptoms are rarely due to local irritations alone. The physician is bound, therefore, to leave no stone unturned before resorting to a measure which the patient may afterwards deeply regret. It is also true that if we determine not to resort to such measures except in the last extremity, we shall often find it possible to get on without them. At the same time, while the physician should conscientiously weigh the objections to the operation, he is equally bound not to forget that it has, in many individual cases, proved of priceless benefit.

Each case should be judged on its own merits, and a physician should take care that his own temperament and bias do not stand in the way of the patient's welfare.

DR. W. T. GAIRDNER, of Glasgow, thought that in Scotland there was not the same reckless surgery which had been alluded to, although the necessity for caution doubtless exists. He could heartily endorse almost everything in Dr. Lusk's paper. He related a case which came under his notice many years ago, of a young lady who suffered positive agony at every menstrual period, and had this occurred in recent years the question of removal of the ovaries would undoubtedly have been raised. She married, and afterwards had only one of these terrible attacks. She became pregnant, and from that time her whole life has been entirely free from any of the former trouble. She has borne nine children, and is an excellent mother. A case of this kind, before the mind of everybody who is placed in contact with the question of excising the ovaries of an unmarried woman, will be of service.

DR. C. C. LEE said that for the past ten years he has kept careful records of the cases which he had operated upon for removal of ovaries, either for local disease or diseases of the nervous system. He had yet to see a single case of benefit after a lapse of five years where the removal of the appendages was done for neurotic conditions, and he knew of no case that was not benefited where there was distinctly ascertained structural disease of the appendages. The removal of the uterine appendages is not only legitimate, but is a necessity in all cases where a permanent structural lesion has been made out, and these lesions he thinks can be accurately diagnosed. When this operation is done within proper limitations, it is one of the most beneficent of modern surgical resources.

DR. WATHEN thought the Association deserved thanks for having brought this subject before the profession of this country; the utterances made by its members will tend to control the excesses that have been committed in abdominal and pelvic surgery. He could not conceive of any instance in which ovaries and tubes, considered in a physical examination as normal, should be removed, no matter what the neurotic condition of the patient. He strongly urged the practice of conservative surgery of the pelvis.

DR. LUSK said that his position at present was this: That there are a certain number of cases that he did not know how to treat any better than by taking out the ovaries and tubes. But there are so many cases that he now cures without operation, which five years ago he would have considered it impossible so to cure, that he is in hopes that as time goes on he will still

further reduce the number of cases in which operation is called for. It is necessary that we should spread abroad the idea that the performance of a laparotomy and the removal of ovaries and tubes is not a stupendous form of surgery. He and Dr. Lee were general practitioners, but the cases upon whom they had operated have produced as good results as have been achieved by the most distinguished of the pelvic surgeons.

#### NERVE-STRETCHING IN INVETERATE TRIGEMINAL NEURALGIA.

by DR. JAMES STEWART.

Dr. Stewart confined himself entirely to the consideration of those inveterate cases of trigeminal neuralgia, which are usually described under the name of epileptiform neuralgia. This term includes not only those cases attended by spasm of the facial muscles, but also that class of cases where the neuralgic paroxysm comes on with great suddenness and lasts a few seconds, and which persists for years in spite of all the ordinarily employed external and internal remedies. Of three cases which came under his observation, one was a woman, aged fifty, whom he first saw in November, 1889, who complained of severe neuralgic pains in the left infra-orbital region. The first paroxysm came on twelve years previously, and was attended by profuse flow of saliva. For a period of about two years she had no recurrence of the attacks, but during the past ten years she had many attacks daily during the winter months of these years. She was entirely free during the summer months. She had been perseveringly treated by many different physicians, but with very little relief. Dr. Stewart advised stretching the nerve, and Dr. Shepherd of Montreal performed the operation in December, 1889. She remained entirely free from pain for thirteen months after the operation. In January, 1891, the pain returned in the same spot, with much of its old-time severity, but only lasted a few weeks. For the past six months she has remained entirely free. A second case was a woman, aged sixty-five, who was never affected with neuralgia until after her sixty-first year. For a period of four years she had been troubled with severe darting pains in the region of the right infra-orbital nerve, and for several months before the operation the paroxysms had assumed an extremely severe form. For hours, and even for a day or two at a time, she was not infrequently compelled to remain perfectly quiet in the endeavor to lessen the number of attacks. Dr. Shepherd stretched the right infra-orbital nerve in February, 1890, and with the exception of one severe paroxysm a few hours after the operation, the patient remained entirely free from pain for a period of fourteen months. After this she had on several occasions slight recurring attacks at considerable intervals, but the intensity of the pain never reached what it did in the period previous to the operation. This patient died in August of the present year, from enteritis.

The third patient was a woman eighty years of age. Fifteen years ago she received a severe injury to the right shoulder, involving the brachial plexus; she dates her facial neuralgia from this period. All the teeth in the right upper jaw had been removed, but with little or no beneficial result. Dr. Buller, on January 1<sup>st</sup> of the present year, stretched the infra-orbital very thoroughly, but without any solution of its

continuity, as far as could be judged. All pain ceased from the date of the operation. There was complete loss of sensation and reflexes on the right side of the tonsil, uvula, and soft palate. Four months after the operation there was a return of the old neuralgic pain. Six months after the operation the paroxysms of pain were less frequent and less severe and she spoke of them as being quite bearable then in comparison to what she formerly suffered.

In the three cases reported there was complete relief, lasting in one for fourteen months, in another about twelve months, and the third for four months. These results, although not of a very enduring character, still are sufficiently pronounced to much more than counterbalance the slight danger and distress attending the operation performed.

Dr. Stewart, in looking up the literature of this subject, found but few cases where the patient was kept under observation for a period of nine months after the operation. He believes that the percentage where permanent relief is obtained is very small, probably not more than five per cent.

From study of cases of neurectomy, some 250 cases in all, Dr. Stewart believes that fully twenty per cent. have relief extending from one to three years, and probably ten per cent. are completely cured. The showing from neurectomy is considerably better than from nerve-stretching, but it must be remembered that neurectomy is an operation not devoid of danger. Nerve-stretching is a mild operation and should always be preferred to an extensive neurectomy.

Dr. Stewart has come to the following conclusions: (1) Nerve-stretching gives either complete or great relief in the majority of cases. (2) Relief is not permanent in more than five per cent. of cases. (3) If the pain should return, the operation should be repeated even several times before resorting to a neurectomy or ligature of the common carotid. (4) If the pain is not strictly and always limited to one branch of the nerve, several branches should be stretched. (5) As relief does not always immediately follow the stretching, a second operation should not be undertaken until some time has elapsed.

#### ON THE DISEASES OF THE KIDNEY POPULARLY CALLED BRIGHT'S DISEASE,

by DR. FRANCIS DELAFIELD.

The time has come to abandon the idea that there is such a disease as Bright's disease, and to cease from the attempt to describe varieties of a disease that does not exist. In classifying kidney diseases, we may do so according to their causation, according to the character of the morbid process, or according to the portion of the kidney involved. At the present time a working classification is made most easily according to the character of the morbid process. Such a classification would be as follows: Acute congestion of the kidney; chronic congestion of the kidney; acute degeneration of the kidney; chronic degeneration of the kidney; acute exudative nephritis; acute productive, or diffuse nephritis; chronic productive, or diffuse nephritis, with exudation; chronic productive, or diffuse nephritis, without exudation.

*Congestion*, whether acute or chronic, produces an accumulation of blood in the veins and capillaries of the part affected, causes local symptoms and disturbances of function, and is to be relieved by means addressed to the circulation of the blood. *Degenera-*

tion, whether acute or chronic, produces changes more or less profound in the parts affected; is regularly caused by poisons, by disturbances of circulation, and by other diseases; produces disturbances of function according to its severity; may be itself a cause of inflammation, and can be but little affected by any treatment. *Inflammation* is attended with three essential features, which may occur separately, or together; an escape of the elements of the blood from the vessels, formation of new tissue, and a death of tissue. So we speak of exudative, productive and necrotic inflammations. Exudative inflammation is of short duration, leaves behind it no permanent changes in the parts affected, and can be favorably affected by treatment. Productive inflammation runs an acute, subacute or chronic course. It affects permanent changes in the inflamed parts. Its acute forms are very apt to become chronic. There is much variety as to the relative quantity of exudation and of new tissue. Treatment is not very satisfactory.

DR. W. T. GAIRDNER, of Glasgow, speaking of the term "Bright's disease," said that on the face of it, he did not like it — a disease called after a man. He did not think Bright would have wished or sanctioned the use of his name in connection with this disease. If he (Dr. Gairdner) went down to posterity at all, he hoped that it would not be either in connection with a disease or a pill or a powder. But there must have been something of practical expediency or necessity, felt as such at the time, in connecting Bright's name with this disease. Bright's own position in regard to this disease is a very remarkable one. He does not attempt to theorize about it at all. He stated facts, and carefully guarded himself at all points in the statement of these facts. What Bright said was, that there are some organic diseases of the kidney, that is, diseases attended by permanent changes of structure, which are associated with dropsy and with albumin in the urine, and that the association of these facts was an important clinical indication which should be kept in view in diagnosis. Subsequently, in Guy's Hospital Records, he developed almost all of what we now know: for example, the association of enlargement of the heart, and certain alterations in the arterial system. All this can be found foreshadowed, at least, in his work. He did not approach a generalizing theory of its pathology. He said that some of these different conditions *may* begin in inflammation; he did not say it was so. All who have accepted these doctrines and followed on Bright's lines came to see that Bright's disease was a term which could not be dispensed with at that time. Then came the book of Rayer, which at once took hold of the French school in the same way that Bright's took hold of the English school. Rayer had no difficulty about generalizing and putting forth a theory, and he tried to cover the whole field of Bright's disease under the term "nephritis." This had an unwholesome influence on the French school because, by bringing in so broadly the idea of an inflammation as the elementary pathology of Bright's disease, it led to bad practice; that is, the undue use of the so-called antiphlogistic remedies. They had the fear of inflammation of the kidney before their eyes, and in the case of a dropsy were afraid to make use of diuretics. Then came the three-fold division of Virchow: the intra-tubular or parenchymatous nephritis, the intra-tubular or interstitial form, and the amyloid. This three-fold division, with the great au-

thority of Virchow behind it, has taken hold of the medical mind, and has led my friend and colleague, Dr. Grainger Stewart, to speak of Bright's diseases. The tendency has been too much to make these three forms absolutely distinct from each other, and to overlook what is probably the fact that there must be an underlying unity when they all lead to permanent disorganization of the kidney. Dr. Gairdner believes that the amyloid form is not, properly speaking, a form of Bright's disease, for the amyloid change is not necessarily a disorganizing change. As an illustration of this, he cited the case of a patient who had reached the last degree of exhaustion connected with amyloid disease supervening upon disease of his bones, who recovered completely after the performance of an operation. Of the two other classes (the intra-tubular and the extra-tubular) there is a fairly broad clinical distinction between the extremes, but when the subject is investigated further, I think we shall find something pathologically in common, which really forms the essential change in a case of Bright's disease.

DR. W. T. COUNCILMAN considered Dr. Delafield's proposition to classify the kidney diseases, not according to the appearance of the kidney but according to the nature of the pathological process in the kidney, as an exceedingly great advance. Dr. Councilman, in his investigations of renal disease at the Johns Hopkins Hospital, had attacked the subject from another point of view, — from an etiological standpoint. Lesions of the kidney can be divided into two classes: focal lesions and diffuse lesions. He had endeavored to trace, in a general way, how these lesions took place. We might assume that the kidney, so long as it receives its blood-supply in normal amount, so long as that blood-supply is of a normal nature, so long as there is no change in the blood itself, and so long as the products of excretion of the kidney are not interfered with, the tubes remain normal in the kidney for all time. In order to have change, there must be some alteration in the character of the blood, in the amount of blood going to the kidneys, in the pressure of blood, or some interference with the removal of the excretion of the kidney. The focal lesions are produced by substances which reach the kidney in an insoluble form; these are essentially the bacterial lesions of the kidney, the tubercles, abscesses, and so on. The other great class of cases, the diffused lesions, are due to soluble substances brought to the kidney. These substances being in solution in the blood are distributed all over the kidney, and the lesions, in consequence, will be diffused. These are the lesions which come on in consequence of the infectious diseases, and in consequence of chemical substances whose nature we do not very well know, and constitute a number of the varieties of chronic diffused Bright's disease. These injurious substances can also reach the kidneys by way of the ureters. Congestion of the kidney, either acute or chronic passive congestion, produce certain degenerations in the epithelium of the kidney. And further, there are certain lesions produced in the kidney by the result of the interference in the circulation by changes in the kidney alone; and here come in the very important changes in the kidney which always accompany the amyloid process. Amyloid changes are almost essentially confined to the glomeruli, and we know that all the blood of the circulation of the kidney passes through the glomeruli first, and these being diseased we have certain degenerative lesions in the epithelium of

the kidney elsewhere directly in consequence. We can have, as a result of all these lesions, conditions which will be very similar indeed. It is possible that we can have almost the same macroscopic appearance of the kidney in a case where circulation is interfered with, as in general endarteritis, and from the long-continued action of some soluble morbid agent. In consequence of both of these processes, changes are produced in the kidneys, consisting essentially of degenerations followed by increase of connective tissue. We can have a granular contracted kidney in any of these conditions.

DR. V. C. VAUGHN thought Dr. Delafield was certainly working in the right direction. It has been very unfortunate that we have been so long hampered with the term Bright's disease. We all recognize that there are diseases different in their origin and etiology and demanding different treatment, all coming under the head of Bright's disease. The quicker we can get away from the idea of unity in these diseases the more rapid progress we shall make.

#### HOW MUCH SHALL BE INCLUDED IN THE TERM "ALBUMIN?"

by DR. ANDREW H. SMITH.

With the discussion of Bright's disease the question of the significance of albuminuria is inseparably connected. But as preliminary to determining whether we have albumin in the urine, we must decide as to what, or rather how much, shall be included in the term albumin. Some studies which I have recently made seem to show that albumin, or, to be more precise, serum albumin, is a very indefinite term, in fact that it does not represent any definite chemical substance. Thus I find that a solution of Merck's pure serum albumin in water will give when boiled a precipitate. This being filtered out and the filtrate treated with nitric acid, a second precipitate is formed. Filtering again, and adding a strong solution of mercuric bichloride, we get a third precipitate. Filtering once more, and agitating the filtrate with ether, a precipitate is formed which rises slowly to the surface. Finally, after filtering this out, agitation with chloroform throws down a dense white fifth precipitate. Here then we have five distinct precipitates formed successively from the same portion of a solution of pure serum albumin, and I have no reason to suppose that I have exhausted the possibilities in this direction. From these observations, coupled with the fact that chemists have never been able to fix upon a definite formula for albumin, no two specimens giving the same result on analysis, I think we are justified in the inference that there is no body having a definite chemical composition to which the name albumin can be affixed, but rather that albumin like the contents of a brewer's vat, is a transition substance, the exact composition of which changes by insensible gradation as the transition advances, and that any given specimen is simply a mixture of different gradations, some of which respond to one test and some to another.

Finally, what sort of a precipitate shall be considered to decide whether a patient has or has not albuminuria? Shall it be the one obtained by heat, or the one by nitric acid, or the one by picric acid, or the one by Fehling's test, or the one by Millard's test, or the one by bichloride, or the one by ether, or the one by chloroform, or the one by some other "more

delicate" test yet to be discovered? It is very important that this should be settled before we pass sentence upon a patient, particularly as at least two of the precipitates which I have obtained from serum albumin can be obtained from the urine of every person in this hall. Normal urine agitated with ether will give a more or less abundant precipitate precisely similar to that from serum albumin. Filtering this out, and agitating the filtrate with chloroform, we get a precipitate which again is precisely similar to that from serum albumin! Filtering this out, and agitating the filtrate with chloroform, we get a precipitate which again is precisely similar to that from serum albumin. The inference which I draw from this, is that under normal conditions there is an excess of nutritive material in the blood, and that a considerable share of the albuminous portion of this excess passes out through the kidneys, without having become at any time a part of the tissue. This overflow contains albuminoid material in various stages of elaboration, any stage of which may cause a response to some one test but not to others. There is no definite line of demarcation between those albuminoid substances which are normally present in the urine and those which are abnormal. The most we can say is that urine which responds to the coarser tests, such as heat and nitric acid, is more likely to be abnormal, while the more "delicate" tests may show normal as well as abnormal constituents of the urine. Certainly ether and chloroform are tests so "delicate" that if their evidence were admitted, all the world would have albuminuria.

DR. W. T. GAIRDNER: With respect to the substances which Dr. Smith obtains from normal urine, he did not believe it had any pathological analogy with the albumin which is found in Bright's disease. He would never pronounce the fate of a man upon any other test than those of nitric acid and heat.

DR. VAUGHN thought that all of these so-called "delicate" tests for albumin were fallacious. It is better to overlook a case of Bright's disease that actually exists than to pronounce a man in perfect health as having Bright's disease.

DR. J. P. C. GRIFFITH, after examining the specimen exhibited by Dr. Smith, containing the precipitate obtained by the chloroform, thought that it was not a precipitate but an emulsion.

DR. SMITH said that he had taken the precipitate with chloroform, dried it at a temperature of 150° and obtained a solid residuum. We are constantly liable, he thought, in our "delicate" tests to confound albumin with something that is normally in the urine.

#### BRADYCARDIA IN ACUTE ARTICULAR RHEUMATISM, by DR. I. E. ATKINSON, of Baltimore.

Bradycardia, or abnormal infrequency of the pulsations of the heart, is present, according to several recent writers, whenever the heart-beats fall below sixty in a minute. It is undoubtedly a very rare symptom during the course of acute articular rheumatism, and nearly all writers upon this disorder do not refer to it. Statistics show that it is usually during convalescence from, and not in the course of rheumatic fever that bradycardia has been encountered, and that when thus occurring it usually has its origin in a cause common to convalescence from a number of acute febrile disorders. But it is not the object of the paper to discuss bradycardia as an epiphenomenon of convalescence;

the rare phenomenon of bradycardia during the course of and not after acute rheumatism is more especially considered, first in its clinical and then in its etiological relations.

Dr. Atkinson here gave in detail two cases which had come under his own observation, and one case each from Blachez, Peacock, Bouillaud and MacDonnell. In his first case pericarditis was present, and a systolic basic murmur developed and persisted. In his second case there was pericarditis with slight effusion. Pericarditis was also present in the cases of Blanchez and Bouillaud. In Peacock's case there was sharp precordial pain and a systolic basic murmur developed; and in MacDonnell's case a soft blowing systolic murmur appeared and disappeared. Blanchez thought the bradycardia in his case was intimately related with the inflammation of the serous membrane, probably to the more or less profound modification which the superficial muscular layers from the heart experience from the pericarditis present. Most writers upon diseases of the heart refer to the occasional slowing of heart action in pericarditis, though, since the phenomenon is quite rare, specific examples of such occurrence are quite uncommon. Graves has known the pulse to be less frequent than in health during the first stage of pericarditis. Ozanam notes that a rare pulse at the beginning of an acute cardiac affection ordinarily indicates the invasion of pericarditis or of endocarditis. Here the phenomenon of slowness, as contrasted with the ordinary pulse of inflammation, is accounted for by an excitation of the vagus nerve. Similar observations are made by a number of writers. There are a number of recorded observations of bradycardia developing during the period of serous effusion into the pericardial sac. Dr. D. W. Prentiss, in 1889, in a paper read before the Association, presented abstracts of ninety-one cases of slow pulse which he had found recorded in medical literature. In two of these cases the bradycardia was associated with pericardial effusion.

In view of the various factors that it is possible to imagine as provocative of bradycardia it would be unwise to deny the power of rheumatic principles circulating in the blood to slow the action of the heart, working upon the muscle itself or upon its nerves, as is assumed by Grob; and it would be equally unwise to assert that when bradycardia develops during acute rheumatism, it may not depend upon rheumatic myocarditis, with or without endo- or peri-cardial inflammation. It would seem, also, that not only may bradycardia arising during the height of the rheumatic fever but, not infrequently, that developing during the decline and even after the subsidence of this affection be attributable to conditions in which the inhibitory nerve of the heart may be involved in irritation and that therefore, Traube's theory of "heart-tire" may not answer for all, even post-rheumatic bradycardia.

The following conclusions were presented: (1) Bradycardia is observed rarely during the active stage of acute inflammatory rheumatism. It occurs with greater frequency during convalescence from this disease. (2) When it occurs during convalescence, in most cases, probably, it is identical with bradycardia following acute febrile diseases of widely different nature and directly the result of the febrile action itself upon the innervation or musculature of the heart. (3) When it occurs during the active stage of rheumatic fever, it probably depends upon endocarditis or pericarditis or myocarditis (primary or secondary, by

extension) whereby the inhibitory nerves of the heart are implicated and consequently stimulated. Even where the physical signs of cardiac inflammation are absent, bradycardia occurring during the acute stage of rheumatism may be secondary to undetected myocarditis stimulating the vagus nerve. (4) It is possible, but exceedingly improbable, that this symptom may follow the action of the rheumatic *noxa* upon the cardiac muscle or nervous system directly.

Dr. PEPPER related a very interesting case which he had recently seen, where, without any apparent cause, a middle-aged man became the subject of "diaphragmatic palpitation" with bradycardia. He has attacks with respiration about 110, and pulse 50; he pants like a hunting dog after a chase for hours and days, while able to go about and take food and sleep. Another peculiar case of bradycardia under his observation was that of a child with erysipelas of the face. There was a sudden recession of the erysipelas with development of acute local peritonitis in the epigastric region, with high temperature and bradycardia. Gradually the peritoneal symptoms subsided and the pulse, respiration and temperature became normal. Dr. Pepper had seen a number of cases in his practice, of acute pericarditis with bradycardia.

Dr. ORD, of London, was much interested in Dr. Atkinson's paper, because it called attention to the occurrence of slow pulse where the temperature is still raised. For many years he has thought it probable that the pneumo-gastric nerve itself plays an important part in the phenomena of acute rheumatism. We see structures, the myocardium, the peri- and endo-cardium, with which it has important relations, taking on active inflammation quite out of all proportion, in many cases, to the intensity of the joint inflammation, but having a very considerable relation with the temperature. Then there is the remarkable phenomenon of the skin perspiring profusely when the fever is running high. And there is a great tendency to hyperpyrexia. All these seem to indicate that the system of the pneumo-gastric exercises an important part in the phenomena of acute rheumatism.

For years he has had the idea that acute rheumatism is to be regarded as the work of nerves excited in various ways—by strain, by reflex irritation. This would most probably explain the acute rheumatism which is apt to follow parturition, and the acute rheumatism which occurs in lactation, and that following in acute quinsy.

During the past six or seven years he has been examining carefully a large number of cases of gastric ulcer in which anaemia was well marked, and has found physical signs which seem to indicate the process of pericarditis with effusion; in some cases endocarditis with affection of the mitral valve; and in some cases myocarditis. If in these cases, without fever, without prostration, there is a setting up of inflammation about the heart, how can we account for the inflammatory process coming about? It is probably through reflex irritation conveyed up and down the fibres of the pneumo-gastric. Of course, both the gastric ulcer and the cardiac mischief may be the result of the pneumo-gastric becoming irritated in an anemic person.

Referring to Dr. Atkinson's cases, he thought the bradycardia in them would fit in with his idea of the pneumo-gastric exercising some function in acute rheumatism.

(To be continued.)

## AMERICAN SURGICAL ASSOCIATION.

TWELFTH ANNUAL MEETING HELD IN WASHINGTON,  
SEPT. 22-25, 1891.

(Concluded from No. 15, page 381.)

## FRIDAY.—THIRD DAY.

THE committee to which was referred the suggestions in the President's address, offered the following resolution, which was adopted:

"Resolved, That the President appoint a committee with authority to confer with the friends and admirers of Professor S. D. Gross, and with the profession at large, for the initiation of a movement on the part of the Association, having for its object the erection of a monument to Dr. Gross, in the city of Washington."

As the matter is an important one, the President stated that he would announce the committee in a few days.

## TREATMENT OF FRACTURES INVOLVING THE ELBOW-JOINT.

by DR. LEWIS A. STIMSON, of New York.

The special interest of the subject arises from the frequency with which fractures of the lower end of the humerus are followed by more or less diminution of the functions of the elbow-joint, and by deformity of the region or of the limb. The paper was devoted mainly to a consideration of the causes of these unfavorable results.

*Causes of Limitation of Motion.*—Permanent stiffness after simple fracture is commonly due to change in the shape of the articular surfaces or in their relations to one another, that destroys the coincidence of the axis of curvature with that of motion; or to an overgrowth of bone upon the surface of the humerus, arresting the movement of the olecranon or coronoid process; or to more or less extensive ossification of the ligaments and capsule.

Overgrowth of bone from traumatism is more frequent in the young than in the adult. As limitation of motion may be caused by bony outgrowth from the humerus, itself the result of a persistent displacement of a fragment or of separation of the periosteum, the most efficient way to prevent it lies in an exact diagnosis and reduction of displacement and in the avoidance of any subsequent irritation of the periosteum.

Limitation of motion from thickening of the capsule and peri-articular tissues by the products of inflammation, is, as a rule, a temporary condition. In the more permanent form the lesions are more extensive; the soft tissues are torn and a true cicatrix results. The thickened tissue may become ossified in whole or in part. This cause of limitation has been attributed, but improperly so, to prolonged immobilization, and has led to the practice of passive motion in the early stage, with the object of preventing its occurrence. Observation and experiment has, however, shown that immobilization is not itself a cause of ankylosis, but that it is an efficient agent against inflammation, and that passive motion is powerless to prevent ankylosis when conditions contributory thereto are present. Passive motion, therefore, is either harmful or useless. The primary cause of the exudation and of the proliferation of connective tissue that are the anatomical detachments to motion is, of course, the original traumatism, the secondary cause is the following reaction. The only factor that can be increased or diminished by treatment is the second, that is, the inflammatory

reaction. Rest is universally admitted to be the best antiphlogistic measure that can be applied to an inflamed joint. An important disadvantage of rest at once suggests itself, namely, that the torn tissues may unite with shortening. Both clinical observation and theoretical considerations indicate that passive motion in the early stage does not avoid this disadvantage, but actually increases it. In the present state of our knowledge it seems that a certain amount of limitation is unavoidable. Massage, however, hastens the absorption of exudation and the restoration of mobility, as does also permanent elevation or suspension of the limb. Reunion with shortening may be opposed by change in the attitude of the limb every few days. At a later period passive motion has its value, but in the early stages it is to be avoided.

In regard to deformity, reference was made to only one, that commonly known as the "gun-stock" deformity, due to unreduced displacement of the internal or external condyle. In order to avoid this deformity, the displacement should be reduced by pressure upon the fragment or by abduction of the extended forearm until its outward deviation is equal to that of its fellow, and immobilization by dressings that will not reproduce the displacement.

*Treatment.*—The first element in the treatment is the reduction of the displacement; if necessary, an anæsthetic should be employed. In supra-condyloid fractures permanent traction is usually necessary to overcome the displacing action of the flexors and extensors. This can be effected by vertical suspension of the limb, the patient being kept in bed, or by a weight suspended from the upper part of the flexed forearm while the patient is erect. The former method was recommended for the first fortnight of treatment, especially in compound fractures. Suspension is made by strips of adhesive plaster placed along the front and back of the forearm, and attached to the support by india-rubber cords or a weight and pulley. In simple fractures the other method may be employed. The limb is encased in plaster-of-Paris, with the elbow at a right angle, the wrist being placed in a sling and a weight not exceeding five pounds suspended from the elbow.

In inter-condyloid fractures with marked separation, there is no practicable means of surely maintaining reduction, and considerable limitation is to be expected. In these cases a broader, heavy posterior splint, covering about two-thirds of the circumference of the limb, the elbow being at a right angle, was recommended.

In fracture of either condyle the treatment is by a posterior rectangular splint either of metal or plaster. The forearm has been supported across the chest by a sling at the wrist. In some cases treatment in full extension has been employed. After this method has been used for the first ten days or fortnight, recourse is had to the position with the elbow at a right angle.

Gentle massage will hasten convalescence. It may be advisable to change the position of the limb during treatment; and if great limitation is to be expected, that attitude should be given to the joint in which, if still, the usefulness of the limb will be greatest. In supra-condyloid and inter-condyloid fractures, the splint should be worn six weeks, and in fractures of the condyles for about four weeks. After removal of the splint, the arm should for a few days be supported in a sling. If necessary, passive motion may at this time be resorted to, to increase the range of motion.

DR. N. P. DANDRIDGE, of Cincinnati, agreed with what had been said by the reader of the paper, and referred to two cases occurring under his observation. In one case of simple fracture from great violence, in which non-union had occurred, the arm was treated in a position of almost complete extension. The second case was one in which, after fracture at the elbow-joint a projection of bone pressed upon the median nerve, causing severe pain and atrophy of the muscles in the distribution of the nerve. The case was seen three months after the accident. Removal of the bone was followed by relief of the pain and a gradual restoration of the function of the muscles.

DR. R. A. KINLOCH, of Charleston, thought that in simple fractures about the elbow, if seen early, and the ordinary principles in regard to the treatment of fractures be applied, the result would be good. Probably in a large number of cases we must expect some restriction of movement. The most important element in the treatment is the proper reduction of the fragments. This should be done at once, an anæsthetic being employed if necessary. The proper reduction of the fragments is determined by testing the functions of the joint. The second indication is to retain the fragments in the proper position. If the case is treated with intelligence, it makes little difference what way the splint is applied, or whether it is treated in flexion. The position is to be determined largely by the peculiarities of the individual case. He was himself inclined to favor the extended position. In regard to passive motion used early, he thought that it did more harm than good. If the parts have been properly reduced and held in position, and there is no danger of subsequent trouble, passive motion may begin in three or four weeks.

DR. E. M. MOORE, of Rochester: In a fracture of the internal condyle the cause of the displacement is the flexor muscles, and to relax these muscles the arm is to be placed in the flexed position. In fractures of the external condyle, he had also found this position the preferable one, for when the forearm is flexed, the dense fascia on the front of the arm is rendered tense and acts as an efficient splint. He objected to the extended position entirely. He treats all fractures about the elbow-joint, with the exception of fractures of the olecranon, in the rectangular position for the first ten days or two weeks. Lateral splints are used with the object of pressing the fragments together. After the tenth day the fracture is dressed every other day, the angle of the splint being changed a little each time so that the arm passes from almost complete flexion to almost complete extension. He had never had the slightest difficulty in any case since adopting this mode of treatment.

DR. JAMES M. CANN, Pittsburgh, said that it was not always easy to determine the exact nature of these fractures about the elbow-joint, even with the patient under the influence of an anæsthetic. While the patient is under the anæsthetic the preliminary dressing should be applied. He recommended the use of the internal angular splint, preferably that suggested by Dr. Packard. He did not favor the use of passive motion at an early stage. Passive motion should not be resorted to prior to the twentieth day.

DR. JOHN B. ROBERTS, Philadelphia, thought that the teaching advocated by some of the speakers was to a large extent dangerous and incorrect, that is, that injuries about the elbow-joint should be treated in the

flexed position. He believed that except in unusual cases these fractures should be treated in the extended position, according to the doctrine advocated by Dr. Allis. In this way the gun-stock deformity is avoided. He now approached fractures of the elbow with the same certainty of getting a good result as he did fractures of the lower end of the radius.

DR. S. H. WEEKS, Portland, dwelt upon the fact that all authorities, with few exceptions, advised the flexed position in the treatment of fractures about the elbow-joint. Until there was more positive evidence of the value of the extended position, he thought it better to continue to treat these fractures in the flexed position. He employed passive motion in a modified way. After two weeks' treatment the splints are removed, and the joint moved gently, but not sufficiently to cause pain. This simply alters the relations of the parts without doing any damage.

DR. L. McLANE TIFFANY, Baltimore, thought that, as good results were reported from various dissimilar methods of treatment, we must conclude that the prognosis of elbow injuries depended more upon the patient than upon the surgeon. Fracture of the elbow is rare in adults and common in children; and in children, with reasonably good treatment, there should be a good result, and by the time adult age was reached, the motion would be almost perfect. In the adult the prognosis is more grave. He had had good results both with the flexed and with the extended position. In compound fractures, the secret lies in the relief of tension, irrespective of the apparatus employed. Incision up and down the arm, through the strong fascia, should be made as freely as may be required.

#### RETRO-PERITONEAL TUMORS: THEIR ANATOMICAL RELATIONS, PATHOLOGY, DIAGNOSIS AND TREATMENT, WITH REPORT OF CASES,

by DR. ALBERT VAN DER VEER, of Albany.

As our experience in abdominal surgery increases, we find that there are yet many problems that confront us; and of these problems there are none which require more careful research and are capable of greater improvement, both in operative management and in prognosis, than new growths arising from the retro-peritoneal space. In order to bring this subject more fully to the attention of the Association, the following cases are reported:

CASE I. Miss S., age forty-two years, consulted the author in March, 1882, on account of a tumor located in the back. This was first noticed fifteen years previously. Examination showed a large tumor attached to the right side of the spine at the level of the first lumbar vertebra. It seemed attached to surrounding tissues, of a smooth contour, and hard to the touch. Operation was advised, but declined. The tumor continued to increase in size until November, 1888, when she died from other causes. The autopsy showed the origin of the growth to be the connective tissue about the right kidney. It was encapsulated, and could have been easily removed. It weighed eight pounds. The microscope revealed the presence of fat and myxomatous tissue, with an abundant small, round-cell infiltration.

CASE II. Mr. V., age forty-one years, married, was first seen May 28, 1889. Five years ago strained his back. The pain following this has not been relieved by any treatment. Three months ago he became worse. The abdomen began to enlarge. The

pain was more severe. He lost appetite and flesh. The ankles became oedematous, and a distressing cough developed. The urine was scanty and high-colored, but free from albumin and casts. The abdomen was more prominent on the right side. Fluctuation could not be elicited, but palpation gave an impression similar to that of a lipomatous tumor. On the right side there was flatness from the nipple to the crest of the ileum, with the exception of a narrow space along the border of the ribs, where there was a zone of resonance. The probability of the growth arising from the kidney was strong, and an exploratory abdominal section advised.

This was done June 1, 1889, an incision five inches long being made over the external border of the right rectus muscle. The growth was reached and the capsule divided, but from its attachments it seemed futile to attempt its removal. The patient recovered from the operation, and for a considerable period was relieved of pain. The growth continued to increase in size, and the patient died October 21, 1889. The tumor, which weighed fifty-six pounds, originated behind the peritoneum, and was attached to the right kidney. The microscope showed it to be an adipose tumor, presenting a condition of myxo-sarcoma with sarcomatous infiltration.

CASE III. Mr. N., age thirty-nine, a brass-worker by occupation, began to have vague abdominal symptoms late in the year 1888, with failure of flesh and strength. In June, 1889, he developed jaundice, and a tumor was found in the left hypochochriac and lumbar region. This was as large as a child's head. An exploratory operation was advised, but refused. It was believed that the growth was connected with the left kidney. The tumor continued to grow; and in November, 1889, the patient died. The tumor was found to have sprung from the region of the left suprarenal capsule, and involved it; it also surrounded the kidney. It weighed six and one-eighth pounds. The microscope showed an appearance similar to that in Case II, but with a greater preponderance of sarcomatous and myxomatous elements.

A careful study of the reported cases and of the literature of the subject impresses one with the belief that the most frequent origin of these growths is in the connective tissue of the capsule of the kidney, and that the next most frequent seat is the supra-renal capsule. None of these tumors can be said to be absolutely benign, even those which are made up entirely of histological elements, such as lipoma-fibroma or myxoma. While they show no great tendency to recurrence after complete removal, yet from the great size to which they develop and their tendency to undergo degenerative changes, they cannot be classed as innocent growths.

In many of the reported cases the origin is not stated; and indeed it would, from the subsequent changes in anatomical relations, seem quite impossible to determine the exact origin of many of the large retro-peritoneal growths. They almost always present themselves in the line of least resistance, that is, anteriorly. A careful study of these tumors shows them to be of a mixed variety, containing both the elements of the lipoma and myxoma tissues, which are histologically very closely associated. Fat is developed from embryonal mucin, and in post-fetal life occupies those spaces in the economy which later in the fetus is of myxomatous elements. Doubtless many of these growths arise, under suitable conditions, from congenital neoplasms. The growths often become cystic,

and reach immense proportions. They often present a numerous, round-cell infiltration, pointing to a sarcomatous element. Sarcoma, either in its typical form or in combination with other tissues, often occurs.

**Diagnosis.**—There is not a single symptom that is pathogenic, and the diagnosis is more dependent upon the process of exclusion. Tumors of the other abdominal and pelvic organs, as well as aneurisms and tumors of the abdominal wall, must be excluded. As already stated, many of these tumors have their origin in the capsule of the kidney or the connective tissue surrounding it. These present, in their earlier stages at least, physical signs differing in no respect from tumors of the nephritic parenchyma. In none of the cases reported has renal hæmorrhage or albuminuria with or without casts occurred—conditions which are the rule with tumors of the parenchyma of the kidney. A valuable adjunct in the diagnosis consists in noting the relation of the tumor to the intestinal tube, as shown by the insufflation of hydrogen gas.

**Prognosis.**—Without operative interference there is but one termination, the rapidity with which the fatal result is reached varies with the character of the growth. The mean duration of life after the discovery of the tumor is about nine months. Operative treatment offers much promise. The immediate mortality of the operation is great, yet from the hopelessness of the condition, it is to be urged with great earnestness.

In operations for the removal of retro-peritoneal growths, the choice of incision will usually fall in the line of the linea semilunaris. By the separation of the peritoneum from the internal border of the tumor, it may be attached to the internal border of the abdominal wound, making the whole field of operation extra-peritoneal. The incision of the posterior fold of the peritoneum should be external to the attachment of the mesentery of the colon, although not absolutely necessary. In the removal of the growth by enucleation, care should be taken to determine the source of the blood-supply and the relation of the great vessels. There are likely to be large, thin-walled veins deep in the wound, requiring ligature. At times it will be found necessary to remove the kidney with the tumor. As in all abdominal work, the operator should be prepared for any and every complication. After enucleation, the cavity must be thoroughly drained. The after-treatment is the same as after other severe abdominal sections.

Like all other conditions in surgery, there is certainly a better understanding of these cases going on.

A more correct and early diagnosis, as is the case in all that pertains to medicine and surgery, will surely bring a larger percentage of recoveries.

These are purely surgical cases, no medicines, no mineral waters or baths, electricity or other lines of therapeutics having, as yet, been of any service.

To the paper was appended a complete bibliography of retro-peritoneal new growths.

#### INTRA-THORACIC SURGERY: BRONCHOTOMY THROUGH THE CHEST WALLS FOR FOREIGN BODIES IMPACTED IN THE BRONCHUS,

by DR. DEFORREST WILLARD, Philadelphia.

Dr. Willard gave the results of a number of experiments on dogs, in which an opening was made in the chest walls, one or more ribs excised, and the bronchus thus reached either anteriorly or posteriorly. The operations were all fatal.

The following conclusions were presented:

(1) In dogs, the bronchus can be reached, either anteriorly or posteriorly, through the chest walls; but the anatomical position is in such close proximity to large and important structures, that safe incision is a matter of extreme difficulty and danger.

(2) Bronchotomy through the walls of the thorax is an operation attended with great shock from collapse of the lungs, and until the technique is farther advanced, is liable to result in immediate death.

(3) Collapse of the lung is more serious in a healthy organ than in one previously crippled by disease.

(4) The serious inherent difficulties are shock, suffocation from lung collapse, enormous risks of hæmorrhage from pulmonary vessels, injury of or interference with the pneumogastric nerve, great and fatal delays owing to the exaggerated movements of the root of the lung caused by the excessive dyspnea.

(5) Closure of the bronchial slit is slow and dangerous. To leave it open causes increasing pneumothorax by its valve action, and also permits the entrance of septic air into the pleural cavity.

(6) Although a foreign body can be reached by this route, yet removal is hazardous. To secure a subsequent complete cure seems, in the present state of knowledge, very problematical.

(7) When the presence of a foreign body in the bronchus is definitely determined, and primary voluntary expulsion has not been accomplished, there is great danger in permitting it to remain, even though it may but partially obstruct the tube. The risks, both of immediate and of subsequent inflammation, are serious.

(8) Low tracheotomy is then advisable when the presence of a foreign body is certain. It adds but little to the risks, and affords easier escape for the object, even when extraction is not feasible.

(9) *Subsequent dangers arise from severe and prolonged instrumentation, not from tracheotomy.*

(10) Voluntary expulsion is more probable after than before tracheotomy.

(11) Tracheotomy is permissible even after an object has been long in position, unless serious lung changes have resulted.

(12) The question of tracheotomy will depend largely upon the form, size and character of the foreign body.

(13) The term bronchotomy should be limited to an opening of the bronchus, and should not be employed to designate higher operations.

(14) The risks from thoracotomy and bronchotomy following unsuccessful tracheotomy are much greater than the dangers incurred by permitting the foreign body to remain.

DR. J. R. WEIST, of Richmond, said that from a study of one thousand cases in which a foreign body was impacted in a bronchus, he had reached the conclusion that the chances of the patient were better if left alone than if an operation of what was formerly called bronchotomy was done.

DR. S. H. WEEKS, of Portland, thought that in these cases tracheotomy should be performed, as this affords a chance of reaching the foreign body, and also offers a chance for the spontaneous expulsion of the body. It occasionally happens that the body is forced up against the vocal cords and then falls back, or else suffocates the patient before relief could be afforded. He reported the case of a child ten years old, who had gotten into the trachea a screw-cap that was used to close

a pocket flask. It had been there several days before the patient came under observation. It was decided to open the trachea. This was done, and the patient suspended; but the foreign body did not escape. The patient was then placed in the horizontal position, and the attempt was made to remove the cap with forceps. It could be felt, but not grasped. After working unsuccessfully for some time, the patient was again suspended, and the attempt with the forceps renewed, and at once the body was grasped and removed. The patient made a perfect recovery.

DR. KINGSTON, of Montreal, reported a case in which he had removed an artificial incisor tooth with its attachments from the trachea, where it had remained for three months. The operation necessitated prolonged manipulation, but was followed by no bad results.

DR. HOWARD MARSH, England, thought that on account of the danger of leaving the foreign body in the bronchus, the uncertainty in regard to the possibility of removal until the attempt is made, and the safety of tracheotomy, the operation should be performed. The operation should be performed in all these cases, as it gives the patient a chance where otherwise he perhaps has none.

MR. ARTHUR EDWARD DURNHAM, of London, agreed with the author of the paper that the operation through the chest wall was a dangerous and doubtful procedure. The more he saw of these cases the more satisfied was he that the proper thing to do where there is clear evidence that a foreign body is impacted in the bronchus, is to open the trachea low down, and endeavor to remove the foreign body or to facilitate its spontaneous expulsion. This opinion was the result of considerable experience.

DR. LOUIS A. STIMSON read a paper on  
OLD UNREDUCED DISLOCATIONS OF THE ELBOW.

The following papers were read by title:

FRACTURES INVOLVING THE UPPER THIRD OF THE FEMUR, EXCLUSIVE OF THE NECK,

by DR. O. H. ALLIS, Philadelphia.

FRACTURES OF THE BONES WHICH FORM THE ELBOW-JOINT, AND THEIR TREATMENT,

by DR. LEVI C. LANE, San Francisco.

HEMIPLEGIA WITH APHASIA, FOLLOWING LIGATURE OF THE COMMON CAROTID ARTERY,

by DR. J. EWING MEARS, Philadelphia.

INVESTIGATION OF PISTOL-SHOT WOUNDS OF THE SKULL, AND THEIR TREATMENT,<sup>1</sup>

by DR. E. H. BRADFORD, Boston.

THE RESULTS OF EXPERIMENTS IN THE FILLING OF BONES FOLLOWING OPERATIONS FOR CARIES,

by DR. E. H. BRADFORD, Boston.

After extending a vote of thanks to the retiring President, the Association adjourned, to meet in Boston, Mass., in June, 1892.

CONSIDERING the present condition of the streets of Boston, notices like the following, to be seen at the ends of open street-cars, are especially timely:

AVOID—1776—ACCIDENTS.

DO NOT GET OFF THIS CAR WHILE IT IS IN MOTION.

<sup>1</sup> See page 100 of the Journal.

THE BOSTON

## Medical and Surgical Journal.

THURSDAY, OCTOBER 15, 1891.

*A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.*

*SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.*

*All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.*

*All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.*

*Remittances should be made by money-order, draft or registered letter, payable to*

DAMRELL & UPHAM,  
283 WASHINGTON STREET, BOSTON, MASS.

## ADVICE TO THE MEDICAL STUDENT.

WITH the opening of the medical schools the British medical journals come to us laden, as usual at this period of the year, with introductory addresses. Some of these are of more than usual interest, contain less than usual of the banal and commonplace, and offer less than usual material for those who argue in favor of the abolition of such addresses. One of these lectures reviews the work and life of Pasteur, with which it adorns the tale of progress in scientific medicine, and points the appropriate moral. And, by the way, it is a little curious that, although Pasteur's name and discoveries are referred to in several addresses, those of Koch are hardly mentioned. Another lecturer, Sir J. Crichton-Browne, discourses eloquently and sagaciously upon "Old Age," and, notwithstanding the strangeness of the subject for the ears of the young and its previous treatment by the pen of Cicero, has found much to say, and a way to say it that makes it good hearing or reading for any period of life. "Depend upon it, the best antiseptic against senile decay is an active interest in human affairs, and that those keep young longest who love most"—this is a good apothegm, which cannot be offered too soon by those having experience of active life to those about to fit themselves for entering upon it.

Mr. Victor Horsley, addressing the medical students of University College, London, chose the practical subject of: "What are the factors which shall enable us to succeed in the practice of our profession, — not merely to succeed in gaining a livelihood, but in properly fulfilling the other part of our duty, the furtherance of general medical science by the accumulation of fresh facts, and the invention of fresh procedures for the relief of suffering humanity?" In opening his address, Mr. Horsley says:

"I had considerable hesitation in accepting the responsibility of addressing you to-day, from the feeling that it would be impossible for me to say anything to you which had not been vigorously and eloquently discussed by one or other of my predecessors. On inquiry, however, I found that, almost without exception, these addresses were devoted either to the considera-

tion of medical politics or of recent changes in medical education, or, finally, to the panegyric of medicine as a splendid and noble profession. On this last point it is, I believe, quite unnecessary for me to further dilate. In the first place, you would not, I am sure, have selected it as your means of gaining a livelihood had you not been fully convinced of its merits; and, secondly, so striking an object-lesson in disinterestedness is being daily afforded by the members of the profession already engaged in it that no words of mine are needed to emphasize its virtues more clearly. I do not myself know of any other profession, the constant aim of whose members is to deprive themselves of their own sources of income for the good of the public, yet this Quixotic act is that which is exemplified by all those who are striving to forward sanitary work and to strike at the roots of disease. I may perhaps add that the public are not apparently conscious of this view of the case, or organized attacks on such individuals as Pasteur, Lister, and others and their followers, would not be permitted, and the rewards which would be assigned to such benefactors of society would more adequately represent their services. As, however, I have been saying, disinterestedness is a distinguishing mark of the profession, and both the public and the State seem determined that it shall continue to be so."

Leaving, therefore, at one side questions of medical politics and medical education, Mr. Horsley proceeds to consider how one is to make his way in the profession. Looking at our work, from the point of view of practice as a commercial process, it seems to him that the problem to be considered resolves itself into, What do our patients ask for from us? If a patient or his friends come to you, there are three things which he or they wish to know: (1) What is the matter with him? (2) How will it end? (3) How can he be relieved or cured? Now, the first of these is diagnosis; the second, prognosis; and the third, treatment. Of these, to his mind the second — namely, prognosis — is unquestionably the most important to the patient and his friends, and it is plain why this should be so. For in the large majority of cases, even if their nature be explained in the easiest possible and most popular manner, the public learn little or nothing from the statement that they have such and such a disease; and even if, as appears to be the developing fashion, they buy a dictionary of medicine, and read up the article which treats of their particular complaint, they are very little wiser. They come, therefore, for special or expert knowledge of what the disease will do, how it will end, and what will be their future, and this is the most difficult part of our work as well as the most important. In attempting to equip themselves for this purpose students will be fulfilling not only the dictates of a logical analysis of scientific education, but will, at the same time, accomplish much for the advancement of the highest interests of our profession.

There are, it seems to Mr. Horsley, always two phases of any education, whether technical or primary: the first is that wherein, consciously or unconsciously, we are training ourselves how to learn — that is, how to observe, and how to form accurate deductions; and the second is that wherein we are accumulating facts. To us, both are of vital importance, and it is an extraordinary thing to his mind that there are persons, — he is sorry to say, actually in the profession itself — who, very ignorant themselves, do not understand the absolute necessity of our acquiring, for the purposes of

diagnosis, a precise knowledge of the minutest points in anatomy and physiology. It is not merely not a waste of time for students to devote themselves as much as possible to this work, but it is an absolute necessity if they are to fulfil one of the first requirements of success — namely, the power of forming an accurate diagnosis.

That the modern student, if completely educated, is, both as a diagnostician and as deviser of treatment, infinitely superior to the rule-of-thumb production of the old apprenticeship system, Mr. Horsley is quite convinced. He should, however, secure for himself in the hospitals opportunities, not merely for practical experience, but also for taking responsibility. As a coping-stone to the educational edifice, the student should add, if possible, the great advantage of foreign travel and experience, for in no other profession — except the law — is there necessary such a profound and varied knowledge of human nature, and in no other way can it be so profitably acquired.

The dangers and impediments which tend to block a medical man's progress and mar his success, after he has made a start, Mr. Horsley divides under two headings, professional and social. As far as lies in his power, the young practitioner should try to keep himself abreast of the progress in medical science, by a post-graduate course and the regular reading of medical journals. One should always do one's best, and then not be too much cast down by the miscarriage of one's hopes in a given case. Questions of mere ethics should be easily settled, but questions involving honor admit of no compromise; and blackmail should never be submitted to.

One should remember, that, while he himself is a unit in a large profession, that profession is but one among various communities of men, and should, therefore, think both of what he owes to his profession and science as well as to the community at large.

Finally, the medical profession is one in which honest work is sure to succeed, and in which the actual work is always interesting and always advancing.

The apparatus which he uses for the irrigation is simply a fountain syringe with the "recipient" or "fountain" of tin; this fountain is hung on the wall over the patient; the rubber tubing which is connected with the lower extremity of the fountain ends in a small glass tube tapering at the point like a dropping-tube. A spring "catch" on some part of the tubing interrupts the current of liquid at will. When the fountain is charged with the solution and ready for action, the head of the child is held by an assistant, the tongue depressed, and the jet directed into the mouth and posterior pharynx with sufficient force to detach and remove the false membranes if they happen to be loose.

Pariset likes best the position in which the child is held with the head forward and a little downward. Where the child is very feeble, it may be supported upon the arm of the assistant with the face turned toward the floor. In this position it may be more difficult to perform the irrigations, but there is more certainty that the liquid will flow back again, and not be swallowed in any quantity.

As for the quantity of the liquid to be used in each irrigation, this must be left to the judgment of the physician; it may not amount to more than three or four ounces each time, but in grave cases the oftener the irrigation is practised the better. The use of the irrigations does not make unnecessary other remedial measures, such as the frequent administration of stimulants.

Pariset makes some remarks as to the action of salicylic acid on false membranes which, if true, are of great practical importance. He believes he ascertained by experiment that this acid is destructive to diphtheritic formations; in distilled water, the false membrane was simply disaggregated, and this disaggregation took place slowly, while in solutions of different strengths of salicylic acid, the exudate disappeared rapidly; at the end of a few minutes, nothing was found but the meshes of the net-work serving for support to the cells of the exudation. The stronger the solution of salicylic acid the more prompt and complete was the disappearance of the exudate.

Pariset has, moreover, noticed that in diphtheritic throats that have been irrigated with the salicylic solutions, false membranes, when once detached, are reproduced more slowly and imperfectly than when the throat is cleared by any other process; he hence concludes that the mucous membrane is favorably modified by the salicylic acid, and rendered unfit for the reproduction of the diphtheritic patches, and hence, for the culture of *Loëffer's bacillus*.

Salicylic acid in weak solutions has been often employed locally in cases of diphtheritic angina. Berthold, of Dresden, derived benefit from such applications in stomatitis, thrush, and diphtheritic sore throat. Moizard and Bergeron claimed success from the use of this remedy, and Gouthuin, out of thirty-one cases treated by swabbings with salicylic solutions, did not lose a patient. D'Espine and Picot have also treated

#### TREATMENT OF DIPHTHERIA BY IRRIGATIONS OF SALICYLIC ACID.

PARISOT, of Thillot in Vosges, has published in the *Bulletin Général de Thérapeutique*, for September 15, 1891, an article in which he highly commends in diphtheria the employment of irrigations of salicylic acid (1-1000), and affirms that whereas before resorting to this method of treatment, the mortality from that disease as occurring in his practice was large — ten cases out of every fourteen — in a recent epidemic in which he has relied on the irrigations, there were only five fatal cases out of every twenty-four.

The formula which this writer employs is as follows:

R	Acid salicylic . . . . .	1 gm.
	Water . . . . .	500 gms.
	Alcohol (90%) . . . . .	20 " M.

Dissolve the salicylic acid in the alcohol, and add the water.

several cases by irrigations with solutions of varying strength, and have been pleased with the results.

Weise was one of the first to advocate the topical use of this acid in diphtheria. His method is to begin treatment by painting the throat with a tolerably strong solution, then he causes a weaker solution to be inhaled; half an hour afterwards he gives the patient a swallow of wine; in another half-hour, a spoonful of a strong solution of benzoate of soda, then a little more wine, and when two hours come around, the series begins again with swabbing or gargling with the salicylic solution. The result of his success, according to Guelpa, from whose paper we quote,<sup>1</sup> is, that he does not let half an hour during the day elapse (the interval is a little longer during the night) without irrigating or otherwise cleansing the throat of the patient with some efficient antiseptic substance, wine, solution of salicylic acid or benzoate of soda. To many the profit of so much meddling, either locally or constitutionally, will seem doubtful.

#### MEDICAL NOTES.

**PROFESSOR VIRCHOW'S BIRTHDAY.**—A meeting was held at the library of the Johns Hopkins Hospital last Tuesday, in honor of Professor Virchow's seventieth birthday.

**INFLUENZA IN PORTUGAL.**—During the month of August the northern parts of Portugal were visited by a severe epidemic of influenza, which in a large proportion of cases assumed a form resembling typhoid fever. A good many cases also occurred in Lisbon, and in one week of August the mortality from pneumonia, and in another that from intestinal catarrh, was exceptionally large.

#### BOSTON AND NEW ENGLAND.

**HARVARD UNIVERSITY.**—The Medical Department of Harvard University has an entering class of 170, and in the Law School 185 new students have entered, of whom 115 are in the first-year class.

**DR. ALBERT DAY,** the President of the Association for the Study and Cure of Inebriety, celebrates his seventieth birthday to-day. The Association will hold a public meeting in the Chapel of the Washingtonian Home at eight o'clock, to be preceded by a reception in the parlor of the Home.

**THE FIRING OF CANNON ON BOSTON COMMON.**—The fortunate existence of an open space in the very centre of a large city is surely no excuse for discharging cannon in it, causing a far distinctly felt for a mile in all directions. To say nothing of the unwelcome surprise with which a healthy person is greeted when one of our artillery companies are practising or celebrating, the number of sick persons and nervous invalids within a short distance of the Common is not small, and of the many may be more or less seriously affected by such bombardments as we from time to time receive.

<sup>1</sup> See Medical Practice, German, Dec., March, 1889.

**THE MARGARET PILLSBURY HOSPITAL AT CONCORD, N. H.**—Early in the year 1890, Hon. George A. Pillsbury, of Minneapolis, Minn., announced his purpose to build for the hospital association in Concord, a hospital as a memorial to his wife, to be known as the Margaret Pillsbury General Hospital. The building has been completed, and was last week formally turned over by Mr. Pillsbury to the association, with appropriate ceremonies. It is 124 by 70 feet, cost about \$100,000, and will accommodate fifty patients.

#### Miscellany.

##### BOSTON DISPENSARY.

The statistics of this institution for the year ending September 30, 1891, are as follows:

The number of new patients treated at the Central Office is 25,859, classified as follows:

Medical Department.—Men, 3,276; women, 5,267; children, 3,071; total, 11,614.

Surgical Department.—Men, 2,445; women, 1,167; children, 818; total, 4,430.

Skin Department.—Men, 665; women, 462; children, 261; total, 1,388.

Department for Diseases of the Nervous System.—Men, 700; women, 499; children, 82; total, 1,281.

Department for Diseases of the Throat and Nose.—Men, 915; women, 866; children, 507; total, 2,288.

Department for Diseases of Women.—Women, 803; total, 803.

Department for Diseases of the Eye.—Men, 287; women, 345; children, 282; total, 914.

Department for Diseases of the Ear.—Men, 177; women, 168; children, 230; total, 575.

Department for Diseases of the Genito-Urinary System.—Men, 1,236; women, 31; children, 1; total, 1,268.

Department for Diseases of the Rectum.—Men, 129; women, 68; children, 12; total, 209.

Orthopedic Department.—Men, 37; women, 26; children, 33; total, 96.

Dental Department.—Men, 232; women, 319; children, 442; total, 993.

The number of visits made by patients, old and new, at the Central Office is 59,892, classified as follows: Medical, 21,382; surgical, 38,510; total, 59,892. The number of patients treated in the Districts is 16,257 (including 438 cases of midwifery), classified as follows: Men, 2,996; women, 6,276; children, 6,985; total, 16,257. The results of treatment in the Districts are as follows:

Discharged, cured or relieved . . . . .	15,019
Removed to hospitals . . . . .	879
Died . . . . .	341
Remaining under treatment . . . . .	83
	16,322
Under treatment at last annual report . . . . .	65
	16,257

The number of patients treated at the Central Office and in the Districts is 42,116.

The number of cases of midwifery attended during the year . . . . . 438

The number of cases since July, 1856 . . . . . 6,604

Whole number of patients treated since October, 1798, 1,115,109

Whole number of patients treated since July, 1856 . . . . . 996,306

Average daily attendance at Central Office during the year . . . . . 196

Largest number present any one day, May 11th . . . . . 317

Smallest number present any one day, March 4th . . . . . 102

Number of recipes put up at the Central Office during the year . . . . . 62,716

Number of house recipes . . . . . 50,116

Number of district recipes . . . . . 12,600

Largest number of recipes put up in one day, April 27th, 1881 . . . . . 361

Smallest number of recipes put up in one day, August 28th . . . . . 97

Number of paid recipes . . . . . 66,601

Number of free recipes . . . . .	6,055
Number of paid dental patients . . . . .	925
Number of free dental patients . . . . .	68

The list of medical officers for the ensuing year is as follows:

**Surgeons:** Drs. Edward O. Otis, Frederic M. Briggs, Arthur K. Stone, Paul Thorndike. **Physicians:** Drs. Robert Disbrow, John Dixwell, Thomas M. Roteh, Claudius M. Jones, Harold Williams, George M. Garland, Edward M. Buckingham, William C. Emerson, Robert B. Dixon, Russell Sturgis, Thomas F. Sherman, James S. Howe, William F. Temple, Henry Jackson, Henry C. Baldwin, Robert W. Greenleaf, William S. Boardman, Samuel Breck.

**Department for Diseases of the Skin.**—Drs. Francis B. Greenough, Abner Post.

**Department for Diseases of the Nervous System.**—Drs. William S. Bullard, John A. Jeffries, Elliott G. Brackett.

**Department for Diseases of the Throat and Nose.**—Drs. John W. Farlow, J. Payson Clark, Algernon Coolidge, Jr., Frederic C. Cobb.

**Department for Diseases of Women.**—Drs. Francis H. Davenport, John B. Swift, Rufus A. Kingman, George Haven.

**Department for Diseases of the Eye.**—Drs. William D. Hall, Edwin E. Jack.

**Department for Diseases of the Ear.**—Drs. William S. Bryant, Wallace Preble, Ernest E. Doble.

**Department for Diseases of the Genito-Urinary System.**—Drs. George H. Tilden, Francis S. Watson, Hayward W. Cushing, Gardner W. Allen.

**Department for Diseases of the Rectum.**—Drs. Walter J. Otis, William D. Hodges.

**Obstetric Department.**—Dr. Charles M. Green. **Assistants,** Drs. Edward Reynolds, Charles W. Townsend.

**Orthopedic Department.**—Dr. Augustus Thorndike.

**Pathologist.**—Dr. Edward M. Greene.

**Dentist.**—Dr. Alexander H. Fisher.

**District Physicians.**—Drs. Willis B. McMichael, George A. Sargent, George A. Craig, Richard Sprague, Joel E. Goldthwait, Chauncey R. Burr, George H. Washburn, William H. Prescott, Edward L. Twombly, James R. Draper, Charles D. Fillebrown.

**Apothecary.**—Frederick H. Dudley. **Assistant Apothecary,** Joseph S. Lang.

WM. H. H. HASTINGS, M.D., *Supt.*

## SUBMEMBRANEOUS LOCAL TREATMENT OF DIPHThERIA.

At the last meeting of the American Medical Association, Dr. A. Seibert, of New York, reported thirty-five cases of pharyngeal diphtheria treated by submembranous injections, with a demonstration of the methods employed. He pointed out that the various antiseptics applied to the throat do not reach and destroy the bacilli underlying the false membrane. In order to effect this object, he injects by means of hypodermic needle-points, an antiseptic into the inflamed mucous membrane under the affected part. He uses a hypodermic syringe, to which can be attached a long tube terminating in a flat, hollow extremity, from which projects a number of short hypodermic needles. A variety of shapes enable these needle points to be pressed into any part of the affected pharyngeal mucous membrane. After placing the syringe in position he presses the needles into the submucous tissue and then injects about twenty millimetres of chlorine water. This liquid he finds to be the most suitable, the safest, and the strongest antiseptic for this purpose. Of the cases reported he had only lost two, and then from complications. The general treatment is at the same time carried out with careful attention to detail.

## THERAPEUTIC NOTES.

**EUCROPHEN, A NEW SUBSTITUTE FOR IODOFORM.**—By the action of iodine on members of the phenol series in alkaline solution a number of antiseptic substances have been formed, of which aristol (dithymol-di-iodide) has already been largely used. Goldmann<sup>1</sup> describes another to which the name eucrophen has been given. Chemically it is isobutyl-ortho-kresol iodide, and is formed by the action of iodine on isobutyl-ortho-kresol. It is an amorphous yellow powder with a peculiar aromatic smell, which disappears almost entirely when it is dissolved in or mixed with some menstruum; it is insoluble in water and glycerine, but very soluble in alcohol, ether, chloroform, and collodion. In fatty oil it dissolves to the extent of twenty-five per cent. Its solution in all these menstrua is apt to decompose, and deposits an iodine compound which is soluble in water. In contact with water or with secretions iodine is slowly given off, and on this depends no doubt its antiseptic action. Mixed with fat, lanolin, or vaseline it keeps well, but it cannot be prescribed along with starch, or with most metals, as the free iodine causes discoloration. It can be used in all cases where iodoform is useful, and has the advantages over it of being non-poisonous, of having comparatively little odor, and of being so light that a small weight can be dusted over a large area.

**RAISING CHILDREN IN BRAN.**<sup>2</sup>—This method was proposed by M. Puc at the *Société Normande d'Hygiène Pratique*. It consists of a cradle which has the wooden bottom taken out, and is then lined with a strong cloth. In this is placed sterilized bran to nearly half a yard in depth. A hair pillow is used. The baby has only a short flannel shirt on and is naked from the navel downward. It is covered with a woollen blanket, and a wool-lined dress is kept to put it in when taken up for nursing. It has thus full liberty of movement in all its limbs, while its dejections pass at once into the pure bran, keeping the child dry and clean, even if there is diarrhoea. This method is a cheap one, the bran not costing as much as diapers.

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 3, 1891, TO OCTOBER 9, 1891.

WILLIAM H. FORWOOD, surgeon, U. S. A., granted leave of absence for one month, on account of sickness.

CORNELIUS T. ALEXANDER, chief medical purveyor, U. S. A., relieved from duties of attending surgeon and examiner of recruits in New York City, and assigned to the charge of the medical purveying depot in that city.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING OCTOBER 10, 1891.

S. H. DICKSON, surgeon, ordered to Marine Barracks, Washington, D. C.

A. F. MORTIMER, surgeon, detached from Marine Barracks, Washington, D. C.

M. P. FERRER, surgeon, ordered to the U. S. S. "Atlanta."

M. L. DRESSER, surgeon, detached from the U. S. S. "Atlanta."

J. R. TAYLOR, surgeon, ordered to the U. S. S. "Chicago."

J. C. WARDEN, medical inspector, detached from the U. S. S. "Chicago," and granted six months' leave.

J. F. KELLEY, passed assistant surgeon, from the U. S. S. "Minnesota," to the Naval Hospital, New York.

R. P. CAY DALL, passed assistant surgeon, from the Naval Hospital, New York, to the Naval Laboratory.

ROBERT BOYD, assistant surgeon, from the Marine Rendezvous, Boston, and to the U. S. S. "Chicago."

A. R. ALFRED, assistant surgeon, from the U. S. S. "Fenn," and to the U. S. S. "Keokuk."

M. L. GATES, assistant surgeon, from the U. S. S. "Keokuk," and to the U. S. S. "Fenn."

HENRY D. AMES, surgeon, ordered as delegate to the Public Health Association, Kansas City, Mo., October 20, 1891.

JAMES H. NORTH, assistant surgeon, resignation accepted September 8, 1891.

## SOCIETY NOTICES.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. — The Section for Clinical Medicine, Pathology and Hygiene will meet at Huntington Hall, Massachusetts Institute of Technology, on Wednesday, October 21st, at 7.45 o'clock.

Dr. L. W. Baker, of Baldwinville, Mass., will read a paper upon "The Care of Epileptics." The subject will be discussed by F. B. Sanborn, Esq., of the Massachusetts State Board of Lunacy and Charity; Mrs. Mary A. Livermore; Dr. C. Irving Fisher, of the State Almshouse at Tewksbury; Dr. S. Fernald, Superintendent of Massachusetts Idiote School; Dr. W. N. Bullard; Dr. T. W. Fisher, Boston Lunatic Asylum; Dr. S. G. Webber; Dr. J. J. Putnam; Dr. Morton Prince; Dr. F. W. Page; and others.

ALBERT N. BLODGETT, M.D., Sec'y, 390 Boylston St.

THE NEW YORK STATE MEDICAL ASSOCIATION will hold its eighth annual meeting Wednesday, Thursday and Friday, October 28, 29 and 30, 1891, at the Mott Memorial Hall, 64 Madison Avenue, near 27th Street, New York City.

E. D. FERGUSON, M.D., Troy, N. Y., Secretary.

THE AMERICAN PUBLIC HEALTH ASSOCIATION will meet at Kansas City, October 20th-23d.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION. — A session will be held in Richmond, Va., November 10-12, 1891.

LOUIS S. MCMURTRY, M.D., President.

W. E. B. DAVIS, M.D., Birmingham, Ala., Secretary.

VERMONT STATE MEDICAL SOCIETY. — The seventy-eighth annual meeting will be held in Burlington, October 15 and 16, 1891.

D. C. HAWLEY, M.D., Burlington, Secretary.

## APPOINTMENTS.

FRANK W. REILLY, M.D., of Chicago, formerly a Surgeon in the Marine-Hospital Service, has been appointed Secretary of the Illinois State Board of Health.

JAMES C. WILSON, M.D., has been appointed Professor of the Practice of Medicine and Clinical Medicine in the Jefferson Medical College, Philadelphia.

ALFRED KING, M.D., has been elected Attending Surgeon of the Maine General Hospital vice F. H. Gerrish, M.D., resigned.

## RECENT DEATHS.

CHRISTOPHER JOHNSTON, M.D., of Baltimore, Md., died October 11th, aged sixty-nine. He graduated from the University of Maryland School of Medicine in 1814. In 1835 he was Lecturer at the University on Physiology, and in 1864 he became Professor of Anatomy and Physiology. In 1869 he became Professor of Surgery, as the successor of Professor N. H. Smith, and in 1881 he resigned his seat, and was appointed Professor Emeritus. He was also Consulting Surgeon to the Johns Hopkins Hospital. He was one of the founders of the pathological and clinical societies, President of the Maryland Academy of Sciences, and President of the Medical and Chirurgical Faculty of Maryland. He was a frequent contributor to scientific and medical literature, and was the author of an article on plastic surgery and skin-grafting in Ashhurst's "Encyclopedia of Surgery."

WILLIAM C. EMERSON, M.D., M.M.S.S., Assistant in Chemistry at the Harvard Medical School, died October 8th, aged thirty-eight. He graduated from Harvard College in the Class of 1875, and from the Medical School in 1880. Soon after graduation he was appointed Assistant in Chemistry, which position he has since held.

DR. G. HAIN, a well-known German military surgeon, died September 7th, aged fifty-seven.

## BOOKS AND PAMPHLETS RECEIVED.

Weight of the Brain in the Feeble-Minded. By A. W. Wilmshurst, M.D. Reprint.

The Proposal. A Dialogue by Zula Maud Woodhull. London: Norgate & Company.

Synopsis of the Lives of Victoria C. Woodhull and Tennessee Claflin. By G. S. Darwin.

Chart of the Metric System. By John K. Rees, Secretary American Metrological Society. New York, 1891.

The Snook-Herr Poisoning. The Official Investigation, Preliminary Examination. By H. M. Goodman, M.D. Reprint, 1891.

Transactions of the State Medical Society of Wisconsin for the Year 1891, Constitution and By-Laws, and List of Members. Charles S. Sheldon, M.D., Madison, Secretary.

## Address.

RUDOLF VIRCHOW, THE MAN AND THE STUDENT.<sup>1</sup>

BY WILLIAM OSLER, M.D.,

Physician and Professor of Medicine in the Johns Hopkins University.

By his commission the physician is sent to the sick, and knowing in his calling neither Jew nor Gentile, bond or free, perhaps he alone rises superior to those differences which separate and make us dwell apart, too often oblivious to the common hopes and common frailties which should bind us together as a race. In his professional relations, though divided by national lines, there remains the feeling that he belongs to a Guild which owes no local allegiance, which has neither king nor country, but whose work is in the world. The Æsculapian temple has given place to the hospital, and the priestly character of the physician has vanished with the ages; still there is left with us a strong feeling of brotherhood, a sense of unity, which the limitations of language, race, and country have not been able to efface. So it has seemed meet and right to gather here this evening to do honor to a man — not of this country, not of our blood — whose life has been spent in the highest interests of humanity, whose special work has revolutionized the science of medicine, whose genius has shed lustre upon our craft.

The century now drawing to a close has seen the realization of much that the wise of old longed for, much of which the earnest spirits of the past had dreamt. It has been a century of release — a time of the loosening of bands and bonds; and medicine, too, after a long enslavement, ecclesiastical and philosophical, received its emancipation. Forsaking the traditions of the elders, and scouting the Shibboleth of schools and sects, she has at last put off the garments of her pride, and with the reed of humility in her hand sits at the feet of her mistress, the new science. Not to any one man can this revolution be ascribed: the *Zeit-geist* was potent, and like a leaven worked even in unwilling minds; but no physician of our time has done more to promote the change, or by his individual efforts to win his generation to accept it, than Rudolf Virchow.

And now, as the shadows lengthen, and ere the twilight deepens, it has seemed right to his many pupils and friends, the world over, to show their love by a gathering in his honor, on this his seventieth birthday. To-day, in Berlin, a *Fest* has been held, in which several hundred members of the profession in this and other countries have been participants, as subscribers to the fund which was organized for the occasion. It seemed well, also, to his pupils who are teachers in this university, and to others, that the event should be marked by a reunion at which we could tell over the story of his life, rejoice in his career, and express the gratitude which we on this side of the Atlantic feel to the great German physician.

Let me first lay before you a brief outline of his life: Rudolf Virchow was born October 13, 1821, at Schivelbein, a small town in Pomerania. Details of his family and of his childhood, which would be so interesting to us, are not available. Educated at the Gymnasium in Berlin, he left it at Easter, 1839, to begin his medical studies, and graduated from the University

of that City in 1843. The following year he became assistant in pathological anatomy to Froriep; and in 1846 he was made prosector, and in 1847 a lecturer at the university. In 1849, on account of his active participation in the political events of the previous year he was dismissed from his university positions, and, as he mentions was only *mit grossen Beschränkungen* reinstated, largely in fact by the efforts of the profession of Berlin, and particularly of the medical societies. In August, 1849, he received a call to the chair of pathological anatomy at Würzburg, a position which he held until 1856, when, by the unanimous vote of the faculty, he was recommended for, and received the appointment which he still holds, namely, professor of pathological anatomy at Berlin. Prior to leaving Berlin he founded, in 1847, his celebrated *Archiv*, which now in its one hundred and twenty-eighth volume, is the greatest storehouse of facts in scientific medicine possessed by us to-day.

Externally, at least, an uneventful, quiet, peaceable life with few changes.

As an illustration of the successful pursuit of various callings, Virchow's career is without parallel in our profession, and this many-sidedness adds greatly to the interest of his life. Dr. Welch will speak of his special labors in the science of pathology; and other aspects will be considered by Dr. Chew and Dr. Friedenwald. I propose to indicate briefly a few traits in his life as a man of science and as a citizen.

From the days of the great Stageirite, who, if he never practised medicine, was at least an asclepiad and an anatomist, the intimate relation of medicine with science, has in no way been better shown than in the long array of physicians who have become distinguished in biological studies. Until the gradual differentiation of subjects, necessitated by the rapid growth of knowledge, the physician, as a matter of course, was a naturalist; and in the present era, from Galen to Huxley, the brightest minds of the profession in all countries, have turned towards science as a recreation or as a pursuit. Alas! that in the present generation, with its strong bent toward specialism, this combination seems more and more impossible. We miss now the quickening spirit and the wiser insight that come with work in a wide field; and in the great cities of this country we look in vain among practising physicians for the successors of Jacob Bigelow of Boston, Holmes of Montreal, Barton of Philadelphia, and others — men who maintained in this matter an honorable tradition, whose names live in natural history societies and academies of natural science, in the founding of which they were mainly instrumental.

In anthropology and archaeology the name of Rudolf Virchow is almost as well known as it is in medicine. Very early in his work we find evidences of this bent in the memorable studies, now forty years ago, on Cretins and on the development of the skull. Not a year has passed since that time without some notable contribution from him on these subjects; and those of us who know only his professional side may well marvel at the industry of the man whose name is quoted as often as in our technical works. In recognition of his remarkable labors in this department, a special anthropological institute was organized in 1881, on the occasion of the twenty-fifth year of his professoriate. In 1881, on returning to Berlin for the first time since

<sup>1</sup> Remarks made at the Virchow celebration, Johns Hopkins University, Baltimore, October 13, 1891.

my student days, I took with me four choice examples of skulls of British Columbian Indians, knowing well how acceptable they would be. In his room at the Pathological Institute, surrounded by crania and skeletons, and directing his celebrated *diener*, who was mending Trojan pottery, I found the professor noting the peculiarities of a set of bones which he had just received from Madeira. Not the warm thanks, nor the cheerful, friendly greeting which he always had for an old student, pleased me half so much as the prompt and decisive identification of the skulls which I had brought, and his rapid sketch of the cranial characters of the North American Indian. The profound expert, not the dilettante student, has characterized all of his work in this line. Even an enumeration with a brief report of his published writings in anthropological and archaeological subjects would take more time than has been allotted to me. Of his relations with Schliemann I must say something, which I could not do so well as in the words used by his friend, Dr. Jacobi, ten years ago: "Schliemann, by whose modern witchcraft holy old Troy is just leaving its tomb, invited Virchow to aid him in his work of discovery of the buried city. He went — partly to aid, partly, as he says, to escape from overwhelming labors at home — only to be engrossed in just as hard work, though of a different nature. In regard to the latter, Schliemann's recent book on 'Ilios' contains some very interesting material. But what has engaged my attention and interest most has been to observe the humanity and indefatigability displayed by the great man in the service of the poor and sick. To read of his constant, practical exertions in behalf of the miserable population of Hissarlik; how he taught the aborigines the efficacy of chamomile and juniper, which grow about them, unnoticed and unused, in rare abundance; how a spring he laid open for archaeological purposes has been called by them 'the physician's' and is believed to have beneficial effects; how he was, on leaving the neighborhood, loaded with flowers, the only thing they had and knew would please him, has charmed me intensely. To admire a great man for his professional labors, eagerly undertaken and successfully carried out, is a great satisfaction to the scientific observer; to be able to love him, in addition, for his philanthropy and warm-heartedness, is a feast of the soul."

Virchow's life-work has been the study of the processes of disease, and in the profession we revere him as the greatest master that has appeared among us since John Hunter. There is another aspect of his work which has been memorable for good to his native city. From the day when, as a young man of twenty-seven, he was sent by the Prussian government to Upper Silesia to study the typhus epidemic, then raging among the half-starved population, he has been one of the most powerful advocates in Germany for sanitary reform; and it is not too much to say that it is largely to his efforts that the city of Berlin owes its magnificent system of drainage. His work in this department has been simply monumental, and characterized by the thoroughness which marks the specialist.

To his exhaustive monographs on camp-diseases, cholera, military medicine, and other cognate subjects, I cannot even refer.

It will be generally acknowledged that in this country doctors are, as a rule, bad citizens, taking little or no interest in civic, state or national politics.

Let me detain you a moment or two longer to tell of one of us, at least, who, in the midst of absorbing pursuits, has found time to serve his city and his country. For more than twenty years Virchow has sat in the Berlin City Council as an alderman, and to no feature in his extraordinary life does the Berliner point with more justifiable pride. It is a combination of qualities only too rare, when the learned professor can leave his laboratory and take his share in practical, municipal work. How much his colleagues have appreciated his efforts has been shown by his election as Vice-president of the Board; and on the occasion of the celebration in 1881, the *Rathhaus* was not only placed at the disposal of the committee, but the expenses of the decorations, etc., were met by the council; and to-day comes word by cable that he has been presented with the freedom of the city.

The years succeeding to Virchow's student days were full of strong political feeling, and with the French Revolution, in 1848, came a general awakening. In Germany the struggle for representative government attracted many of the ardent spirits of our profession, and it was then that Virchow began his political career. The revolution was a failure, and brought nothing to the young prosecutor but dismissal from his public positions. His participation might have been condoned had he not issued a medico-political journal, *Die Medicinische Reform*, the numbers of which are even now very interesting reading, and contain ideas which to-day would be called liberal, but were then revolutionary. It is a striking evidence of the deep impression which even at that time Virchow had made upon his colleagues and the profession, that he was reinstated in his office at the urgent solicitation of the medical societies of the city. He relates in his "*Gedächtnissrede auf Schöntein*," who was the Court physician and not at all in harmony with the views of his prosecutor, that on one occasion in 1848, at a post-mortem, in which the diagnosis of hemorrhage into the brain had been made by the professor, Virchow demonstrated an obstructing embolus in the artery. Schöntein turned to him in a half-vexed, half-joking manner and said, "Sie sehen auch ueberall Barrikaden." His active political life dates from 1862, when he was elected to the lower house from one of the Berlin districts, and has, I believe, sat as member almost continuously from that date. The conditions in Germany have not been favorable to a man of advanced liberal views, and Virchow has been attached to a party which has not been conspicuously successful; but he has been an honest and industrious worker, a supporter of all measures for the relief of the people, a strenuous opponent of all class and repressive legislation, and above all an implacable enemy of absolutism as personified in Bismarck. A man of such strong individuality would make his presence felt in any assembly; and he always commanded the attention of his colleagues, and oftentimes his speeches have been reported fully both in England and in America.

As an illustration of his capacity for varied work, I recall one day in 1884, in which he gave the morning demonstration and lecture at the Pathological Institute, addressed the Town Council at great length on the extension of the canalization scheme, and made a Budget speech in the House, both of which were reported at great length in the papers of the next day.

Naturally, amid such diverse occupations, it has been impossible for him to enter with his old vigor

into the minutiae of pathological anatomy, and his attitude of late years has been critical rather than productive; but his interest in all that pertains to our profession is unabated, and is a feature of his character to which I must allude. Too often with us, in our gatherings and society meetings, the "men of rather and riper years" are conspicuous by their absence. In this respect our great master has set a notable example. Amid cares and worries, social and political, with a thousand and one ties and duties, he has never held aloof from his brethren; but as the weekly medical journals testify, no man in Berlin has been more active, and for years he has held the Presidency of the *Berliner Medicinische Gesellschaft*, one of the most important medical societies of Europe.

Surely the contemplation of a life so noble in its aims, so notable in its achievements, so varied in its pursuits, may well fill us with admiration for the man and with pride that he is a member of our profession. The influence of his work has been deep and far-reaching, and in one way or another has been felt by each one of us. It is well to acknowledge the debt which we every-day practitioners owe to the great leaders and workers in the scientific branches of our art. We dwell too much in corners, and, consumed with the petty cares of a bread-and-butter struggle, forget that outside our routine lie Elysian fields into which we may never have wandered, the tillage of which is not done by our hands, but the fruits of which we of the profession (and you of the public) fully and freely enjoy. The lesson which should sink deepest into our hearts is the answer which a life, such as Virchow's, gives to those who to-day, as in past generations, see only pills and potions in the profession of medicine, and who, utilizing the gains of science, fail to appreciate the dignity and the worth of the methods by which they are attained. As Pausanias pestered Empedocles, even to the end, for the details of the cure of Pantheia, so there are with us still those who, "asking not wisdom, but drugs to charm with," are impatient at the slow progress of science, forgetting that the chaos from which order is now appearing has been in great part dispelled by the work of one still living — by the man whom to-night we delight to honor.

### SOME CONSIDERATIONS UPON LATE SYPHILIS—AND ESPECIALLY LATE HEREDITARY SYPHILIS—MORE PARTICULARLY IN ITS SURGICAL ASPECTS.<sup>1</sup>

BY AUBURN POST, M.D., OF BOSTON.

(Continued from No. 16, page 296.)

ONE of the marked features of modern medicine is the study of intestinal disorders, and the Congress, at its last meeting, gave an impetus to the study, which marks an epoch in American medical history. Has the syphilographer any contribution to make to that study? Is there any syphilitic lesion of the bowel which may confront the surgeon in his search by abdominal section for the cause of intestinal inflammation or obstruction? To show that the question is one liable to arise, let me say that I have recently been called

upon to express an opinion whether in a case of peritonitis occurring in a man who had had syphilis several years ago, there was any reason to suppose his former syphilis had any possible connection with the peritoneal inflammation. In that case, another hypothesis offered a more probable explanation than the previous syphilis, which had lain dormant for several years. But the question as to the possible relationship was raised, which may not be unprofitable to discuss here.

Of course, the processes taking place about the spleen and liver must be taken account of as possible causes of peritonitis. The inflammation resulting in adhesions about these viscera must seldom give rise to symptoms that are recognized, but these are by no means the only possible causes of abdominal inflammation due more or less directly to syphilis.

A case of intestinal dyspepsia of aggravated type has occurred to me, which proves to my mind the existence of syphilitic intestinal difficulties that take the clinical form of severe dyspepsia. This man gave a history of urethritis simply, as antecedent. The extreme difficulty of digestion continued until a periostitis appeared on both tibia, which yielded to iodide of potash. The dyspepsia practically disappeared also. Syphilitic erosions have since destroyed a portion of his pharynx. That is not a unique experience. Similar cases have been reported in varying forms many times. At the present moment I have under my care a young man whose syphilis is scarcely two years old. It has been characterized by occasional symptoms of great severity and tertiary form. The original sore was accompanied by an enormous induration. Headaches have been of marked intensity. There has been an ulceration with a rupia crust on one arm, and a sarcocele. Lately, he has had an attack of severe indigestion, his stomach refused to hold anything more solid than milk and lime-water, and he has been so reduced as to be obliged to give up all occupation for a time. These symptoms do not prove actual lesions of the stomach or intestines, but, if the cutaneous lesions are an index, something more than a mere hyperæmia may be suspected. Our actual knowledge only permits us to call this man one of a class of cases with marked gastric symptoms occurring in syphilis, and amenable to anti-syphilitic treatment.

But such cases as these two occur often enough to establish the fact, that syphilis invades the intestinal tract in some manner with more or less frequency. Some of the intestinal symptoms are doubtless the result of nervous influence of syphilitic origin. Some are possibly caused by disease of the mucous coats, similar in character to cutaneous symptoms, or the lesions of the mucous membranes. It is also fairly well established that very serious lesions of the gastrointestinal tract may take place.

The two extremities of the digestive canal which come within our observation are the subject of syphilitic disease, of ulceration, cicatrization and the formation of fibrous tissue which result in serious strictures. Though attempts have been made to explain the existence of stricture of the rectum as simply an extension of the external ulcerations of primary syphilis, or pseudo syphilis, it is to-day fully established as one of the results of the constitutional infection.

Stricture of the œsophagus is equally well recognized as an occasional result of syphilis.

Post-mortem examinations of cases of stricture of

<sup>1</sup> Read before the Congress of American Physicians and Surgeons, Washington, September 23, 1901.

the rectum have occasionally established the fact of ulcers higher up in the bowels.

Mr. Holmes Coote<sup>4</sup> described a stricture of the rectum and the cicatrix of an ulcer above it resembling the cicatrix of a phagedenic ulcer as seen upon the external integuments, and he quotes a similar case of M. Gosselin.

In *The Medical Times and Gazette*, of March, 18, 1865, vol. I, p. 280, is found a clinical lecture of Mr. Paget's in which he describes a case of syphilitic disease of the rectum and colon. This occurred in a patient who, for seven years, had been afflicted with syphilis, and had been a patient at various hospitals. At her death was found a stricture of the rectum. Above the stricture, and continuous with it, were a series of ulcerations irregularly circular, which Mr. Paget believed to be syphilitic.

Dr. Samuel Wilks, in an article on "The Syphilitic Affections of the Internal Organs,"<sup>5</sup> speaks of "patients, the subjects of syphilis, who had ulceration of the bowels, but whether dependent on the virus must be received with hesitation." He gives three cases of ulceration and stricture of the rectum as the only cases which he can positively connect with syphilis. In the third case cicatrices of old ulcers were found in the sigmoid flexure, and at its lower part it was much constricted.

As one of the possible causes of disease at the ileo-cæcal valve, syphilis must be given a certain amount of consideration in the diagnosis of troubles at that quarter, one of the spots of the human frame demanding a large amount of consideration at the surgeon's hands at the present time.

A case is given by Fenwick<sup>6</sup> of stricture at the ileo-cæcal valve due, in his belief, to syphilis, and he quotes another case from Bartels. In Fenwick's case, the patient suffered with the ordinary symptoms of intestinal obstruction. Colotomy was done, and the opening extended to the small bowel with great temporary relief. In this case there was thickening and ulceration of the mucous membrane at the lower part of the ilium in addition to the stricture of the valve. This man had suffered from syphilis, and had an ulcer of the leg, apparently syphilitic, at the time of his admission.

In the case recorded by Bartels, there was found after death, contraction of the ileo-cæcal valve, and extensive ulcerations of the cæcum and small intestines, and also indurations in the lungs, which were considered as decidedly syphilitic.

In regard to these cases, Dr. Fenwick says: "I am fully convinced that syphilis frequently attacks the mucous membrane of the digestive tract, for I have seen most obstinate cases of gastric ulceration and of dyspepsia following syphilis, which have quickly yielded to the use of iodide of potash, and other remedies of a similar character."

I should hardly have dared to detain you with this recitation of facts known to most or all of you, had not I found a striking confirmation of my suspicions that syphilitic disease of the gastro-intestinal tract is more frequent than recorded diagnosis would lead us to suppose. In looking over the autopsy records of the Boston City Hospital for a purpose to be mentioned later I have found nineteen cases in which the pathologist made the diagnosis of syphilis with more or

less certainty. It was a surprise to find that of that number, there was one case of ulceration of the pharynx, two cases of stricture of the rectum, and in addition — and these are the cases that particularly claim attention — one case in which the mucous membrane of the stomach over the cardiac region was completely eroded; one case in which there were in the duodenum several irregular losses of substance, with elevated edges and hæmorrhagic bases; one case in which there were syphilitic ulcerations and stricture of the large intestine.

These cases are too few to prove anything, but it certainly is worthy of remark that so large a proportion of cases, six out of nineteen, showed signs of trouble with the gastro-intestinal tract. I do not wish to emphasize too much these cases. The only inference I care to draw is to the effect that gastro-intestinal syphilis presents a field for study.

In 1861, in the first edition of that admirable book which has done so much to teach American physicians something about syphilis, Bumstead wrote of the manifestations of syphilis in the brain as follows: "Syphilitic affections of the nervous system present no pathognomonic symptoms by which their specific character may be recognized; and, except in those instances in which manifest lesions of the bones of the skull, face or spine clearly indicate the etiology of the disease, the diagnosis can only be established by the history of the case, the concomitant symptoms and the effect of treatment." The development of our knowledge of nervous syphilis during the thirty years succeeding is one of the very encouraging facts in the outlook for the future. I believe the next thirty years will add an equal amount to our knowledge of syphilis in other directions.

Of disease of the nervous system there is little I can say, save that a large field lies practically unexplored in congenital syphilis. To be sure, we know that nerve degenerations, such as succeed acquired syphilis in the adult, are met with in the subjects of inherited disease, but the recorded cases are few and the diagnosis is obscure.

I must confess that I have felt some hesitation in accepting the general opinion that our idiots and congenital epileptics are seldom syphilitic, but such investigations as I have made tend to confirm the existing opinion. I have been permitted to examine many cases of nervous disease of unknown or doubtful origin, and have seldom found in the child itself conclusive evidence of syphilitic taint, though I have found several children that awakened suspicion. The opportunity for clinical investigation is here very great, but it will require the most painstaking study of a long series of patients in connection with their family history.

A question of interest that arises in connection with the diagnosis of late lesions is as to the amount of influence a negative history should have in a doubtful case. In other words, how far should the failure to elicit a history of previous syphilis influence the diagnosis of a present lesion which may possibly be a late manifestation? Of course, there are cases where the invalid prefers to die rather than admit a previously immoral life, although the position of the physician makes a very great difference in the frankness of the patient. Patients who deliberately lie about their antecedents, are comparatively seldom seen by physi-

<sup>7</sup> Bumstead, first edition, 1861, p. 617.

cians who devote special attention to syphilis. The following incident will illustrate the discrimination occasionally exercised by patients. A woman who had had syphilis called on her old doctor whom she had not seen for some time, with a story of certain ailments and the question whether they could be syphilitic. She had already consulted the doctor whom she considered her family adviser, and he had asked her a series of questions intended to draw out a history of syphilis. The woman said "I have had all the symptoms he asked about, and I saw what he was after, so I promptly said no to all his questions and came straight to you." But the amount of concealed syphilis, the syphilis which is unknown as such to its victim, must be very large. Fournier has published some figures from his private practice, which show that among his female syphilitic patients five and one-half per cent. are cases of non-venereal syphilis, and the non-venereal cases and the women infected by their husbands, together make a total of nearly twenty per cent.

During the years 1888 and 1889 the percentage of syphilis insomium reported in Denmark was 4.7 per cent. of the total number of cases. With so much syphilis innocently acquired, it does not require a great stretch of the imagination to picture other cases which have been so slightly marked as not to attract attention at all.

Dr. Gowers, in his Lettsomian lectures on syphilis and the nervous system, quotes from Dr. Radcliffe Crocker. Dr. Crocker ascertained from his records at the University College Hospital the proportion of cases of tertiary skin eruptions in which there was no history of a chancre. He reported 56 cases of undoubted late syphilitic eruptions, cases that are consecutive and are unselected, and in no less than eleven of these the occurrence of any chancre was unknown. This is a proportion of 20 per cent. "It cannot be doubted, moreover, that besides such cases there must be many more who have no late symptoms whatever to reveal the disease." If 20 per cent. of undoubted syphilodermata of late character deny all knowledge of infection, it does not seem so strange that a large proportion of other late cases should be ignorant of the origin of the disease, and especially is this true of hereditary cases where the 20 per cent. of ignorance of the parents must be augmented by the total ignorance of the child in regard to his antecedents. The value of the antecedent history as an aid to diagnosis seemed worthy of further study, and to test its value I have compared the clinical history with post-mortem records in such cases as I could find of a post-mortem diagnosis of syphilis. For this purpose I have searched the autopsy records of the Boston City Hospital for cases in which the pathologist has committed himself to a diagnosis of syphilis.

The first fact apparent from the search is that the various gentlemen who have served as pathologists have been exceedingly conservative in positively expressing an opinion as to the existence of syphilis. It is the habit of the pathologist to complete his record by a pathological diagnosis, in which he enumerates the various lesions or points of interest in the different organs. In carefully looking over these records, I find but nineteen cases in which the diagnosis of syphilis has been made. Other cases there are in which, from reading the records, the diagnosis might have been made with great probability, but my studies have been confined to the cases in which the pathologist

has used the words syphilis or gumma. Even in these nineteen cases the diagnosis has not always been unreserved. In only nine cases is the diagnosis absolute, including two cases in which the disease was recent and its manifestations evident on the skin. Examinations of the cases of probable diagnosis showed that the probability was so great that it was much nearer the truth to use them than to discard them, as the word "probable," or the interrogation point which modified the diagnosis, often expressed a doubt as to whether the *particular lesion* was syphilitic, rather than a doubt as to the syphilis of the *subject*.

Of the whole nineteen cases, two were recent cases, and ought not to be considered here, leaving seventeen cases in which old syphilis was recognized. In two of these cases the clinical history shows that the patients were unconscious at the time of their admission to the hospital, and, consequently, unable to give any history. This leaves us fifteen cases for consideration. But out of these fifteen cases, in three the clinical record is defective in that syphilis is not mentioned, so that there are only twelve cases in which we have an antecedent history as regards syphilis. Of these twelve cases three absolutely denied syphilis, one denied syphilis, but after questioning said he had a sore on his genitals at the age of six, but nothing since. Four admit chancre, or chancre and bubo. Four only admit syphilis as such. Of course, these cases are few in number, but the fact of a *post mortem* diagnosis gives them a greater value than would belong to the same number of cases without autopsy.

It is possible that the indiscriminate administration of mercury does something to confuse the early history. Whether the early administration of mercury will entirely suppress the earliest appearances of syphilis or not, few would dare to say definitely, but certainly it may have a marked effect in that direction.

To take an example of the class of cases to which I refer, a young man applied for an opinion on the following case:

Six months previous after repeated exposures he had several little sores. They were pronounced to be soft chancres by the physician whom he consulted, and were destroyed with caustic, but internal medication was given and continued, which consisted for part of the time of mercury and potassic iodide. Later, the patient discovered a little blister on the spot of one of the supposed soft sores, which came without exposure, and which he has burned. There is a gland or two in each groin, but none elsewhere. There are a few acneiform lesions on the forehead, which may be syphilitic, but they are not characteristic, and as the patient has always had more or less acne, and has now on the back several scars, and some active papules, it is equally probable that they are the result of the iodide. The spot of the recurrent sore is somewhat hardened, but perhaps no more than the caustic might explain. In that case it was impossible to give a dogmatic opinion. The syphilitic infection is doubtful.

What sort of a history can that man give when the question of tertiaries is discussed? And how easy it would have been for him to overlook the whole affair.

Every prognosis must be a matter of special consideration, just as diagnosis must be. The scars upon the skin, and the cicatrices in the liver tell us not only of the existence of syphilis, but they also tell us that the proper elements of a part have been destroyed, and their place supplied by cicatricial tissue.

Prognosis must always take into account that fact, which is already emphasized by the neurologists, but ignored, to a certain extent at least, by the rest of us.

There is something to be deduced in the matter of treatment, from what has been said in the matter of prognosis. Distinction must be made between the syphilitic lesions themselves and their effects. Antisyphilitic treatment has great power over the active processes of late lesions, but it is powerless to restore the tissue already destroyed, or to diminish the cicatrix already formed. The function of mercury and the iodides ceases with their control over the active process, and the resorption of the specific elements. Surgical operations may occasionally be called in to rectify, or to compensate for the injury caused by loss of tissue and consequent contractions. Strictures of the œsophagus and of the rectum, fully formed by cicatrization, or the formation of fibrous tissue, as well as advanced aneurism, are among the surgical lesions of syphilis that we cannot expect to cure by medication.

Syphilitic cicatrices are no more curable than other cicatrices, whatever may be their origin. If the disease is recognized at its first period, before the active syphilitic process is terminated, or possibly before the cicatrix itself is solid, one may hope for a recovery from antisyphilitic remedies, but it is extremely important to recognize this necessary limitation.

The attempt to destroy syphilitic growths, or to heal syphilitic ulcerations by the application of caustics is, I believe, not uncommon; but in general it may be said that to attempt to destroy by caustics without internal medication, a syphilitic tertiary lesion, is as futile as common. Valuable as caustics are in some cases as adjuncts to proper treatment, used alone they seem to me to stimulate the destructive process rather than control it.

Even when the late forms of syphilis are recognized as such in children, the value of antisyphilitic treatment is not fully appreciated. The late lesions of inherited syphilis are as readily controlled by the antisyphilitics as those of acquired disease. The amount of the iodides that may be administered is very large in most cases.

What is the value of treatment in establishing a retrospective diagnosis? We have seen that certain limits must be set to the powers of medicine. It must also be admitted that mercury and the iodides have certain power over tuberculosis, and perhaps new growths. *A priori*, it seems just as proper to expect mercurials to act favorably on tuberculous lesions as on syphilis, and I believe some of our closest students of external tuberculosis consider that mercury does act favorably on tuberculous lesions, but still recovery of a doubtful lesion under mercury and iodide mercears very decidedly the presumption of its syphilitic origin.

As between external tuberculosis and external syphilis, the therapeutic test is of less value in my opinion than between syphilis and other diseases. It seems to me improper in a doubtful case to hang the diagnosis absolutely on the therapeutic test.

I recognize that what precedes is fragmentary, and I fear most of all, it is true. It is difficult for a man who occupies himself with a subject for a long time to know whether any part of his knowledge may be novel to his neighbors, or how far he may consider that his own experience is the common experience of

all. In what I have said I have tried to distinguish my individual opinion by using the personal pronoun, that no one might imagine that I was enunciating established laws when I was only giving the inference drawn from my own limited experience. I am painfully aware that the subject has only been touched in a few only of its important features.

In conclusion I wish to say, that the study of syphilitic phenomena is a necessity of medical progress. The possibility of syphilis renders uncertain the diagnosis of tuberculosis and cancer, and other malignant forms of disease, and thus renders negative therapeutic and pathological investigations. We need the most careful clinical studies; we need hospitals specially devoted to syphilis; we need to make its study obligatory.

#### A CONTRIBUTION FROM BRAIN SURGERY TO THE STUDY OF THE LOCALIZATION OF THE SENSORY CENTRES IN THE CEREBRAL CORTEX.<sup>1</sup>

BY PHILIP COOMES KNAPP, A.M., M.D.,

Clinical Instructor in Diseases of the Nervous System, Harvard Medical School; Physician for Diseases of the Nervous System to Out-Patients, Boston City Hospital.

THE question of the localization of the sensory centres in the cerebral cortex is still an open one. One set of observers place them in the central region about the fissure of Rolando, another in the limbic lobe. It is not my purpose in the present paper to discuss the question either from the standpoint of physiological experiment or from a summing up of clinical observations. The case I have to report seems, however, to be the most exact observation yet made upon the human subject, and to afford strong evidence in behalf of the hypothesis that the sensory centres are in the Rolando region.

Jeremiah O'Brien, forty-eight, single, a native of New Jersey, a laborer, presented himself at the Boston City Hospital, on March 24, 1890, with the following history: He was formerly well and vigorous. He had indulged somewhat in alcohol, but he denies any venereal disease. At the battle of Chantilly, September 1, 1862, he received a bullet-wound in the head. He was carried to a hospital in Alexandria, where he remained six months. When he left his wound was not healed, and it constantly discharged. Before his injury he was mentally sound, since then his friends say that he has been peculiar and irresponsible. In July, 1863, in New York he got drunk, and, on becoming sober, found that he had enlisted in the navy. He served on the Mississippi as store-keeper on a gun-boat, then joined a fleet preparing for Mexico, and finally took service on a Peruvian iron-clad, where he did some sort of clerical work, keeping records for two years. He wandered about the world, as sailor or stowaway, and finally, in 1872, returned to Boston. For some time about this period he was very dull and did little. Since 1862 there has been a progressive decline in his mental powers, and he was for a time at the Westborough Asylum. His memory has grown very poor, and he admits that he cannot give very accurate statements as to his condition. After his wound he had severe pains in the head occasionally, perhaps once in three or four years, usually starting from the site of the wound. For eight or nine months, or, as he said later, for two years, he has had attacks, in

<sup>1</sup> Read before the American Neurological Association, June, 1890.

which he fell down, his limbs worked, and he became unconscious, remaining unconscious or ignorant of his surroundings for four weeks. He has had four or five of these attacks, but little could be learned in regard to them. His chief complaint now is of these attacks and of headache; he also thinks his mind is weak, and his memory poor, and he has much trouble in talking; the memory at times is wholly gone. He can think of what he wants to say, but cannot say it. His appetite is poor, and he is somewhat costive. He complains also of some soreness of the scalp and growths on the scalp, which have lasted for about four months.

tion of the eyes reveals well-marked myopia in the left eye, but no other anomalies. There is much fibrillary tremor of the lips, face and tongue, and some tremor of the hands. The grasps are of fair strength, and alike on the two sides. All movements are performed a little clumsily, but with good strength and tolerable co-ordination. The sensibility was tested by myself and by Dr. J. A. Jeffries, to whom I am indebted for various observations during the progress of the case, and was found to be unimpaired. His responses, like all other mental processes, were a little slow, but they were accurate. Tests were made of the sensibility to touch, position, motion, location, pain, weight, pressure, heat and cold. The knee-jerks were somewhat exaggerated. The gait was rather slow and shuffling. The chest and abdomen showed nothing remarkable. The urine contained a trace of albumen and an occasional hyaline cast.

The diagnosis was made of a slowly progressive cortical degeneration of traumatic origin. Considering the history of headache starting from the seat of the wound, it seemed possible to obtain some relief for that by trephining. In the early stages of general paralysis, Claye Shaw<sup>2</sup> has trephined, and claims that there is an arrest of symptoms. Since then the operation has been done once or twice by others, but without much benefit. Considering how common remissions are in this disease, it seems at least to be too soon to claim that such trephining can be of any real benefit. In a case, however, of nearly thirty years' standing no improvement was to be thought of; the only hope was that the headache and perhaps the convulsive attacks might be relieved. He was accordingly admitted to the service of Dr. Post, at the City Hospital, who has kindly placed the further records of the case at my disposal, and permitted me to observe the patient.

"Etherized April 11th. The head was shaved, scrubbed with ether and corrosive sublimate solution (1 to 3000). An elastic tourniquet was put about the head from the brow to the occiput. One of the local swellings was incised and proved to be a wen. A semi-circular cut with a radius of an inch and a quarter was made over the left parietal region with the concavity downwards. An old cicatrix was found in the flap. The skin was incised to the bone and reflected with the periosteum. There was considerable bleeding from the vessels of the scalp, which were tied before proceeding. The bone was smooth with a slight grooved depression under the cicatrix. A one-inch trephine was applied at a point corresponding to the most prominent part of the superficial cicatrix, and a button removed. There was considerable hemorrhage from the diploë, and still more on removing the button, the blood coming from a superficial vessel in the cortex wounded by the trephine, which went through the dura. The dura was divided through the centre, and reflected back, and the bleeding point was tied. The dura was slightly thickened, and on turning it back the cortex beneath was found congested and slightly yellower than normal, one point, the size of a pea, being decidedly yellow. This was excised, and a piece of the bone removed. The excised portion showed some increase in the number of blood-vessels, and a thickening of the vessel walls. The nerve fibres and ganglion cells are not materially affected. It being thought advisable to explore the dura further forwards, the incision was enlarged. Rongeur forceps having failed,

1. Writing from dictation, March 26, 1890.

2. Writing from copy, March 26, 1890.

3. Attempt to write name, April 18, 1890.

4. Attempt to write name, May 20, 1890.

Present condition, well developed and nourished. He has a dull, rather demented look, resembling that of a general paralytic. His comprehension seems dull, and his mental processes are all slow. His speech is thick and slurred, and he often hesitates for a word, becoming somewhat irritated and thinking it strange that he cannot say what he wants to. The words he hesitates on are usually nouns. He says this hesitancy for a word occurs also on writing. He can read aloud, repeat what is said, write independently from copy or from dictation, but all the processes are slow, clumsy and inaccurate. The writing seems poor for a man who has kept records for two years. The first example, written March 26th, represents an attempt to write his name and "Boston City Hospital"; the second, to copy from a printed list "Do not give tea or coffee, cake or candy." There is a scar running longitudinally over the left parietal eminence, about two inches from the median line, and crossing the supposed position of the fissure of Rolando. Beneath this the bone seems depressed; and the scar seems in part adherent. The right pupil is larger than the left, both reacting to light and accommodation. Examina-

the bone being hard, a second button was removed just anterior to the first. The dura appeared healthy below this, and the brain seemed normal. The sharp edges of the bone were removed, the wound was irrigated with hot boracic acid solution (1 to 25), and partially closed with interrupted silk sutures. The other wens were removed by trans-fixion and enucleation. A baked dressing was applied. The operation lasted an hour and a half, and at its close the patient's condition was good, the pulse 60 and of good strength, and the respiration regular."

The circle represents the trephine opening; the line crossing it, the line of the fissure of Rolando, as determined by the cyrtometer; the dot, the situation of the lesion of the cortex.

The point of the cortex from which the hemorrhage came seemed to be on the border of a fissure which ran in the general direction of the fissure of Rolando. Measurements made afterwards with a cyrtometer showed that this was a little back of the position of the fissure of Rolando as thus determined. The effort to secure the bleeding point caused some laceration of the cortex just at the posterior edge of this fissure, and the yellow spot removed was just back of the lacerated portion. The whole portion of cortex injured was not over a centimetre and a half in diameter, and the injury did not extend deeper than three millimetres. Even if the fissure was not the fissure of Rolando, the injured portion could not have been more than half an inch behind it, which ought still to involve the ascending parietal convolution. The injured point, furthermore, was about two inches from the median line, a little below the superior frontal sulcus, as marked out by Reid's method, and opposite the second frontal convolution.

"Afternoon. Patient recovered well from ether. Complaints of considerable pain at the seat of operation. Irregular, involuntary movements of right arm, and queer sensations in it. It took some arguing to make him understand it was his hand. If told to move his arm he can do so, but involuntary working of the fingers persists. Sensation in arm impaired. Tongue protruded to left. Right pupil larger than left.

"April 12th. Quite delirious last night. Condition in morning very good. Arm feels better, but involuntary movements continue.

"April 14th. Feels better. General condition good. Pulse regular and strong. More control of arm, but twitching of the fingers is still present, although less marked. This morning localized edema of right upper lid without apparent cause. Dressing loosened."

On the 13th and 14th I visited him and made examinations. There was a loss of power to perform highly purposive actions with the right hand. A command to open the hand would be met with, "I can't do it"; and as he watched the hand and tried to execute the command it would not open. When his attention was directed to something else, however, he would move the arm and open the hand. Similar commands were executed promptly with the left hand. The movements of the right hand were not co-ordinated, and he repeatedly complained that the arm would not go where he wanted it to, and that it would move about involuntarily when he was not looking at it. "When I'm talking to that fellow (on his left), or when I'm asleep, that arm will come up and hit me a devil of a whack on my nose," he would say. The tactile sensibility was very much diminished in the hand and forearm, and somewhat diminished in the upper arm up to the shoulder. The sense of position of the hand and arm, and the sense of motion, were also lost.

April 16th. A more elaborate test of sensibility was made to-day by Dr. Jeffries, who reports: "Loss of contact below elbow to simple touch, diminished as high as shoulder. Sense of pressure and weight diminished, sense of position of arm and joint-motion absent, sense of pain and temperature normal. Constant light rubbing for fifteen seconds perceived as 'something.' Motions not well co-ordinated or adjusted in rate: one minute the arm is strong, the next weak, the next crampy. Grasp of nouns poor, partly due to being flustered. Said he could not read, but did read the address of a letter; said it was curious that he could not do it, and seemed pleased to know that he had. Wrote 'Boston' well, then had difficulty, chiefly muscular. When asked what four and five made, said at once 'nine,' then asked 'does it?' The records add 'Seems better; can talk better. Says pain he now has in head, at seat of operation, is different from what he has been having, and is not so uncomfortable. Can control hand better, but still has some involuntary motion.'

April 18th. He is able to talk fairly well, without hesitating for a word, and seems brighter. Before the operation he had a dull pain across the forehead, but "all the things he used to have, it seems as if he didn't have now." Tactile sensibility is still diminished, but it is better than on the 14th. Sensibility to pain, and temperature good. Can tell that elbow and wrist are moved, but he is still doubtful about movements of the fingers. Sense of position much better. He can move the arm quite well, and the involuntary movements have largely ceased. He tries to write, but has difficulty in keeping the pencil on the paper; it slides up through his fingers. (See Nos. 3 and 4.)

"April 20th. Wound dressed; perfect first intention. Gauze red and dry, no discharge. Stitches removed. Some swelling where one of the wens was removed, but no pus. Irrigation with corrosive sublimate (1 to 3000) and corrosive dressing applied.

"April 23d. Better. Better control of arm." Drs. Jeffries and Prince saw true athetosis of the arm, which I have not seen.

"April 30th. General condition better. Can control arm better. Wound healed. He still has trouble in speech, which he gets around in this way: 'Last night my hand was cold two or three times. It got cold at 11, and then at—you see, I can't say what I want to—7, 8, 9, 10, 11, 12, 1, 2, yes, 2 o'clock, that was when it got warm again.' Strength of arm much improved."

May 28th. For the last four weeks the patient has been in bed most of the time, and has been growing more inert. He is easily flustered and can be laughed out of any statement. He will often answer correctly, and then be uncertain whether his answer is correct or not. He has regained much power in his hand, and constantly practices to see what he can do. A further test of sensibility was made by Dr. Jeffries. "Sense of contact diminished, most marked in the hand, especially on its ulnar border, but it becomes normal or nearly so, before reaching the elbow. Sense of pain and temperature normal. Sense of pressure and joint motion and position diminished. Some trace of ataxia. Sense of weight probably impaired, but it could not be tested accurately. Fibrillary twitching of muscles of ulnar side of right hand."

May 30th. To-day I made a more extensive observation. He has been in bed, not from his own desire, but from a misunderstanding, and he is anxious to be up and about. Mentally his condition seems about the same, but it is very variable. He talks with less hesitation. Simple calculations, the addition of two figures, are not well performed. He professes himself unable to read, but spells out some letters, and occasionally will read a whole word, for example, "Massachusetts." An attempt to write proves a failure; when asked to write his name he puts down B, when told to make a J, he asks "how do you spell it?" Much of the trouble seems muscular. When asked to add 5 and 6 he says 8, then hesitates, thinks, counts, and says 11; when asked to add 3 and 4 he gives it up. He complains of pain about the seat of the wens. His motor power varies from time to time. His grasp is good, but there is a good deal of inco-ordination, tremor of both arms, and an occasional twitch in the right arm. When he tries to write there is a tonic spasm of the hand, the fingers flexed at the metacarpophalangeal joint and extended at the other joints, the thumbs strongly adducted and extended. The elbow jerks are alike. There is also at times some tonic spasm of the arm. The sensibility to touch, position and joint-motion are much impaired, as on the 28th. The temperature chart shows no rise since the operation.

To sum up the case, therefore, we have a man with normal sensibility, and slightly impaired motor power, who has a lesion of the middle third of the left ascending parietal convolution. This is almost immediately followed by a slight and temporary impairment of strictly purposive movement, by a loss of sensibility to touch, pressure, motion and position, and by motor inco-ordination. Sensibility to pain and temperature remain unaffected throughout. The sensory disturbances and inco-ordination persist seven weeks after the operation.

This seems to prove as conclusively as one case can that the sensory centres are in the central convolutions. It is, of course the most utter begging of the

question to assume that there is a coexistent lesion of the limbic lobe, either from a lesion induced by the operation or from an extension of an inflammatory process from the wound—no signs of inflammation being present there. While I do not accept fully Munk's hypothesis that the functions of the central region are purely sensory, nevertheless the symptom-complex presented in this case is in singular accord with the results of Munk's experiments in this region.

The symptom-complex observed in many cases of syringomyelia points to the belief that the tracts for the sensations of pain and temperature are separate from the other sensory tracts. The fact that these sensations were unimpaired in his case, leads us to ascribe to them also independent centres in the cortex. As a therapeutic measure the operation must be regarded as a failure.

On the 11th of May, 1891, I saw him again in consultation with Dr. Alfred Worcester, of Waltham. During the summer he had been fairly well, and he was able to go about and to walk quite a distance. In the autumn he had another convulsive seizure, and since then there had been a marked mental deterioration, and a return of the convulsions. I found him sitting up in bed, but it was impossible to get him to answer questions intelligently. The speech was very slow. He remembered the hospital and my name, but he entirely failed to recognize me. He could still remember certain events of his life, and he retained a fondness for tobacco. He kept saying "I would like to see Dr. Knapp," but he could not comprehend when told that I was present. Sensibility to pain was evidently present in the right arm, but his mental dulness was so great that it was impossible to test the tactile sensibility.

## Clinical Department.

### GYNECOLOGICAL CASES AT THE ST. ELIZABETH'S HOSPITAL.

SERVICE OF F. W. JOHNSON, M.D.

REPORTED BY DR. E. H. ROSS, House-Officer.

(Concluded from No. 16, page 406.)

#### TWO CASES OF CARCINOMA UTERI.

CASE I. M. A., married, thirty-five years of age, entered the hospital December 1st. Has had four children. Two years ago she was examined in the Out-patient Department, and there was no evidence of cancer at that time, but extensive bilateral laceration of the cervix, with hypertrophy of both lips was found. Last fall she was seen at the Carney Hospital Out-patient Department, and the vagina was found filled with an epitheliomatous mass. She had had several severe hemorrhages, and entered St. Elizabeth's Hospital December 1st, anemic and weak from loss of blood.

December 6th. As much of the disease as possible was scraped and cut away, the bleeding controlled by the cauterizer, and the cavity made by the operation was packed with iron cotton.

December 16th. The cavity was packed with cotton wet with a solution of zinc chloride (equal parts by weight of zinc and water). Severe pain followed the application of the zinc, requiring morphine and papine for its relief. An ugly looking hole was left after separation of the slough.

January 24th. Discharged at own request. As far as could be seen, the disease had not returned.

CASE 11. M. B. W., married, fifty-nine years of age, entered the hospital January 11th. A sister, brother, and one nephew died of cancer. Mother of five children; last one born at the age of thirty-nine. Menopause at fifty. Four years ago had a slight hæmorrhage from the vagina, also two or three months later, and occasionally since. Has been growing fleshy during the past two years. Is excessively nervous. Appetite poor. When seen by Dr. Johnson, January, 1890, the disease had already invaded the vaginal walls, and there was reason to suspect that it had extended into the base of the broad ligament on the left side.

In January, 1890, curetting was thoroughly done, and the cautery applied. Again, in September, 1890, the same operation was done. From this she gained in every way, but in December it was found that the disease had returned, at least in one spot.

January 12th. Operation. Curette and cautery were used. Return of disease found to be slight. In seven days the cavity was packed with cotton wrung out of a solution (equal parts by weight) of zinc chloride and water. The caustic caused intense pain, morphia controlling it only in part. A large and deep slough separated.

February 5th. Discharged. Upper part of vagina was almost obliterated by the contraction of cicatricial tissue.

#### FIBROID TUMOR: MENORRHAGIA AND DYSMENORRHEA: ELECTROLYSIS.

M. A. S., single, thirty-six, entered hospital December 22d. Good family history. Menstruates regularly every four weeks; flows six to seven days; saturates fifteen to twenty napkins. Perfectly well during intra-menstrual periods, but when unwell is obliged to give up her occupation as schoolteacher for three days, on account of severe dysmenorrhœa and weakness from loss of blood. Examined under ether by Drs. Johnson and Conant. A symmetrical, non-fluctuating, hard tumor was found in the abdomen, extending as high as the umbilicus, and bulging into the anterior fornix of the vagina. The sound passed seven inches into the cavity of the uterus without causing any hæmorrhage. A diagnosis of fibroid was made.

December 29th. Dr. Conant assisting, the uterus was thoroughly curetted.

January 12th. Discharged.

The first menstrual period was passed without any pain and with the loss of but little blood, but the second menstrual period was by far the worst she had had for years. The flowing was excessive and the pain unusually severe. After the next menstrual period, which was accompanied with the usual amount of pain and loss of blood, she entered the hospital and electrolysis was done. One needle was passed into the tumor just below the umbilicus and to the left of the median line, and the other was passed through the cervical canal and then into the tumor. The full strength of an eight-cell McIntosh galvanic battery with fresh fluid was allowed to pass through the tumor for fifteen minutes. There was no reaction, and in twelve days electrolysis was repeated. The result will be reported when sufficient time has elapsed to show what effect, if any, the electricity exerts on the tumor. Menstruation returned at the regular time. Flowed three

days. Little pain for one hour during the first day. Lost about one-third the usual amount of blood.

#### ONE CASE OF MALIGNANT ADENOMA.

E. J. H., married, no children, thirty-nine years of age, entered the hospital December 31st. Phthisical family history. Grandfather died of cancer. Grandmother died of "bone tumor of the face." Four years ago began to suffer from menorrhagia, which has been steadily increasing. Between menstrual periods has had for months an almost constant vaginal discharge of a clear, watery fluid resembling serum. Menstruation began at thirteen. For the last three years has been unwell every three weeks. Flows two to three weeks; saturates thirty to forty napkins; severe pain in right ovarian region first three to four days. Very anæmic from loss of blood and serum. Appetite and digestion good. Last November uterus was curetted without ether, and a small amount of tissue removed. This was sent to Dr. W. F. Whitney, who made a diagnosis of probable malignant adenoma.

January 1st. Under ether, a thorough examination was made. Extending from the uterus on the right and reaching to the ilium, a mass as large as the fist was discovered. This was apparently an outgrowth of the uterus. It, with the uterus, which was right laterally retroverted, was immovable. This put vaginal hysterectomy out of the question. The uterus was curetted with sharp curettes and pure nitric acid applied inside the body, care being taken to avoid the cervical canal.

January 10th. Discharged.

In March she again entered the hospital. There had been no return of the serous discharge except for a day or two before and one day after menstruation. Menstruation occurred four weeks after the operation; flowed four days; used thirteen napkins; had more than the usual pain in right side. Menstruation again occurred in four weeks; flowed five days; soaked twenty napkins. Had but little pain. Under ether the uterus was again curetted with sharp curettes, and nitric acid applied to endometrium and cervical canal.

Dr. W. F. Whitney reported as follows: "Examination of the scrapings showed numerous velvety scrapings, not very thick and with no very large or polypoid looking masses. Microscopic examination showed large tubular glands with a relatively large amount of intertubular tissue composed of large, somewhat spindle-shaped cells. This looks like simple hyperplastic endometritis."

#### BILATERAL LACERATION OF THE CERVIX: MALIGNANT ADENOMA. OPERATION ON THE CERVIX: UTERUS CURETTED.

M. A. M., married, thirty-eight years of age, entered the hospital January 27th. Has had ten children and one miscarriage. First labor was instrumental. Long, tedious getting up after last confinement, which occurred in December, 1889. Menstruation began at twelve. Since marriage has been unwell every twenty-one to thirty-one days; flows four to five days; soaks ten to fifteen napkins. Constipation. Painful micturition. Constant leucorrhœa. Examination showed ruptured perineum, bilateral laceration of the cervix, with ectropion and erosion, chronic endometritis, and retroversion. Packing was used until the uterus was in good position.

February 9th. The uterus was curetted and an

operation done to overcome the rolling out of the cervical mucous membrane. Dr. Couant assisted. When etherized an examination revealed a small cyst of the left ovary.

Dr. Whitney's report shows the nature of the disease existing inside the uterus. "The specimen from the case of Mrs. M. consisted of numerous relatively thin velvety pieces with a smooth surface. Microscopic examination showed the thickness of these to be made up of large tubular glands with but very little interglandular substance. From the structure it is rather to be classed with the malignant adenomas than with simple hyperplasias, while on the other hand the general look of the fragments is more suggestive of hyperplasia. My own feeling is that it will have a relatively rapid recurrence."

February 12th. Discharged. Operation on cervix a success.

May, 1891. Examination showed that she was pregnant.

#### IMPERFORATE HYMEN WITH RETAINED MENSTRUAL FLUID.

M. K., single, sixteen years of age, entered the hospital January 29th. This patient was kindly sent to me by Dr. G. E. Thompson, and it was the first one of the kind that I had seen. She had had more or less headache every day for two years. Two weeks ago first had difficulty in emptying the bladder and for a few days before entering the hospital it was necessary to use a catheter. Two weeks ago first noticed a swelling at the vulva.

January 30th. Drs. Thompson, Kingman, and Conant present, an examination showed a bulging of a purplish color extending from the meatus urinarius to the anus. The hymen, thick and tense, was imperforate. An opening was made directly through the hymen with the small tip of the Paquin cautery. A pint of thick chocolate-colored fluid having the odor of caramel slowly escaped. The opening was then enlarged upwards and downwards and to the right and left by the cautery. The vagina was thoroughly douched with a 1 to 5000 solution of bichloride and the finger passed in. The vagina was much dilated and the mucous membrane was in large patches devoid of epithelium. Cervix and uterus were pushed backwards and upwards. Os patulous, easily admitting index finger. Cavity of uterus dilated to the size of a hen's egg. Uterus and vagina were then washed out with a 1 to 1000 solution of bichloride. For one week the vagina was douched twice a day with a 1 to 1000 solution of bichloride as it was found that the vagina tended to close up at various points by adhesion of its walls. There was no sepsis owing to antiseptic precautions.

February 10th. Discharged.

March 16th. Examined by Drs. Johnson and Thompson. The vagina was free from adhesions and the hymen admitted without pain the index finger.

#### COMPLETE RUPTURE OF THE PERINEUM. PERFECT RESULT WITH LAWSON TAIT'S OPERATION.

C. K., married, forty-nine years of age, entered the hospital February 16th. Has had twelve children and three abortions. Was torn into the rectum twelve years ago during labor. Has had three children since, the last one seven years ago. No control over rectum for twelve years. Menstruates every three to four

months. Diagnosis: Complete rupture of the perineum extending three-quarters of an inch up the rectum.

February 23d. Tait's flap operation. Drs. Conant and Twombly assisted. Silkworm gut was used for sutures. Union was perfect when the sutures were removed on the ninth day.

March 17th. Discharged, having perfect control over sphincter ani.

## Medical Progress.

### REPORT ON LARYNGOLOGY AND RHINOLOGY.

BY FRANKLIN H. ROOPER, M.D., BOSTON.

#### THE RELATION OF BACTERIOLOGY TO NOSE AND THROAT DISEASES.<sup>1</sup>

At a meeting of the British Laryngological and Rhinological Society, held on Friday evening, March 20th, Dr. John Macintyre, of Glasgow, gave an interesting lecture, introductory to the discussion on the relation of bacteriology to the diseases of the throat and nose. In the course of his lecture Dr. Macintyre discussed the general facts concerning bacteriology, such as classification, vital phenomena, etc., and stated the arguments for and against the vitalistic theory of disease. He demonstrated a large number of specimens of well-known forms of micro-organisms under the microscope, as well as numerous micro-photographs on the screen, and made special reference to those of interest in throat and nose work. He showed several found in the mouth and nose of healthy people, which are apparently harmless, and others found in diseases where there is decomposing material such as in ozana. He referred to the specific forms found in diseases of the lower part of the respiratory tract, as tubercle, lupus, diphtheria, pneumonia, and suppurative diseases. Lastly, he discussed the question, how protection was to be got from the diseases associated with micro-organisms, noting the result of inoculation, and criticised the theory of phagocytosis. He explained some interesting experiments now being made in Glasgow, with reference to the hypodermic injection of chemically pure carbolic acid, which bid fair to demonstrate the possibility of rendering the effects of certain pathogenic micro-organisms inoperative within the body. In considering the possibility of rendering the tissues unsuitable for the growth of organisms after their entrance into the system, he cautioned his audience not to be carried away too hastily by Koch's or Liebreich's methods of treatment for tuberculosis.

#### CYST AND ABSCESS OF THE MIDDLE TURBINATED BONE.

Dr. Grenville Macdonald,<sup>2</sup> of London, has observed five cases of this infrequent affection. The pathological etiology of these cysts, he thinks, is simple enough. The process in all probability begins in an osteophytic periostitis, resulting in a general increase in the size of the bone in every diameter. The free margin of the bone being incurved upon itself, the extension inwards of this border, from the pathological process just mentioned, will bring it in contact, and ultimately in union, with the body of the bone. Thus a cavity may become enclosed and sealed at all points by a similar

<sup>1</sup> Lancet, March 28, 1891.

<sup>2</sup> Lancet, June 20, 1891.

process occurring at the two extremities. Adhesions in various localities are by no means uncommon in the nose, and are fully exemplified in the further history of these cysts. To express it in other words, this bone hypertrophy may result in the production of a cavity, lined with mucous membrane, and generating mucus, which from the lack of outlet gradually distends the cavity into which it is secreted. Thus are acquired the extreme thinness of the cyst walls, and the enormous size sometimes attained, with adhesions to, and distortion of, neighboring structures.

Dr. Macdonald gives the result of the microscopical examination of the cyst wall, which proves that his explanation of the origin of these neoplasms is correct; and he then describes their gross appearances, symptoms, and treatment as follows: "The cysts are found of varying size. When very large they may form adhesions to the septum, inferior turbinated body, and even the floor of the nasal fossa. They invariably produce deviation more or less pronounced of the septum to the opposite side, and sometimes induce a certain amount of flattening of the bridge of the nose from separation of the nasal bones and nasal processes of the superior maxilla. The contents of the cysts are usually mucus, with more or less polypus growth attached to the inner wall.

The symptoms differ in no way from those due to other forms of obstruction, pressure, or irritation within the nose. Thus we find the not uncommon consequence of stenosis in the form of chronic inflammation of the pharynx and larynx, and the further respiratory passages; besides which there may be various auditory troubles due to Eustachian obstruction. External disfigurements, adhesions to neighboring structures, and trigeminal neuralgia may result from pressure, and sneezing and rhinorrhoea from the irritation. In case of abscess there will be a purulent discharge. The diagnosis presents no difficulty. Whenever an osseous tumor presents itself in the middle meatus of such a size that it is obviously something further than a simple osteopytic periostitis, whether presenting an osseous surface covered only by mucous membrane, or whether it is concealed partially or entirely by polypoid growths, the probability is strongly in favor of cyst. When, moreover, these appearances are accompanied by a purulent or fetid discharge, one may safely surmise that he is dealing with a suppurating cyst or abscess of the middle turbinated.

The treatment is simple enough in cases where the tumor has not attained enormous dimensions. The simplest way of effecting removal is to throw a strong snare round the mass and remove as large a portion as possible. The remaining portion of the walls may afterwards be broken away with forceps. When the cyst is very large, and adhesions have formed to neighboring structures, the adhesion must be severed in the manner most easy of accomplishment, that is to say, with the knife or electric cautery. In some cases a saw might be necessary. Then, a sufficiently large hole having been made, a pair of strong forceps is introduced, and the walls torn away piecemeal.

#### RETRO-PHARYNGEAL ABSCESSES OF CHILDREN.

An exhaustive and interesting paper by Dr. Alexander A. Sokoloff, of Moscow,<sup>2</sup> is based mainly on forty cases of typical retro-pharyngeal abscess, and

<sup>2</sup> A. 1. 1. in the *Journal of Laryngology and Rhinology*, May, 1891, by Dr. Victorius Eichen, of Berlin.

sixteen of retro-pharyngeal lymphadenitis, which have come under his observation in St. Olga's and St. Vladimir's Hospitals for Children, in the course of the last four years.

According to his classification, purulent inflammations in the retro-pharyngeal space, may be divided into the following groups: (1) *Single congestive purulent gatherings* in the retro-visceral cervical space, which arise in connection with various inflammatory processes in its vicinity (cervical phlegmon, inflammation of cervical lymphatic glands, periostitis of adjacent bones, etc.). (2) *Tubercular congestive purulent accumulations*, developing in connection with cervical spondylitis. (3) *Proper retro-pharyngeal abscesses*, due to inflammatory processes in the space itself. The latter category may be subdivided into three groups: (a) *Traumatic phlegmon* of the retro-pharyngeal cellular tissue, which is caused by a direct inroad thereinto of pathogenic microbes. (b) *Metastatic Inflammation* of the tissue, produced by the microbes penetrating through the circulation (in cases of small-pox, typhoid fever, scarlatina, etc.). (c) *Suppurative retro-pharyngeal lymphadenitis*, which is induced by the microbes travelling along lymphatic vessels (and arrested in the glands), and constitutes the so-called "idiopathic" retro-pharyngeal abscess of children.

It is seen, therefore, that the author, in common with Verneuil (1842), believes that the "idiopathic" abscess forms, in reality, nothing else than an acute purulent inflammation of the lower retro-pharyngeal lymphatic glands, which are situated at the level of the second and third cervical vertebrae. In support of the pathogenetic theory, he brings forward the following facts: (1) The abscess is almost invariably accompanied by enlargement of deep lymphatic glands on the same side, or on both sides, of the neck. (2) In some cases the retro-pharyngeal suppuration is preceded by a similar process in, or at least a swelling of, the cervical glands. (3) In other cases suppuration of the retro-pharyngeal is followed or accompanied by enlargement of an analogous gland lying symmetrically on the other side of the space. (4) Occasionally, a direct observation allows us to trace an actual metamorphosis of a swollen retro-pharyngeal gland into a suppurating one. (5) The lymphadenitis invariably arises secondarily to pharyngitis of one or other variety (in other words, Dr. Sokoloff denies the existence of an "idiopathic" retro-pharyngeal abscess). (6) The disease in question occurs mainly (in seventy-five per cent. of cases) in children under one year of age, and never attacks those above four; to put it otherwise, it is observed only in patients of an age during which the glands still exist, and never affects older children in whom the organs have already undergone atrophy and disappeared.

As to the peculiar liability of early life to retro-pharyngeal abscess, it is thought to be connected with acute cervical lymphadenitis in general, which, in its turn, may be explained by "a relatively great frequency in little children of primary peripheral inflammation or traumatic lesions about the head and its cavities."

With regard to the symptomatology of retro-pharyngeal abscesses in general, and retro-pharyngeal lymphadenitis in particular, the author draws attention to the fact that disturbances of swallowing and breathing may be sometimes absent altogether, the affection running a latent course; hence a frequent digital ex-

amination of the pharynx in infants is advised, more especially in those cases where there is present enlargement of deep cervical glands.

Passing to an operative treatment, Dr. Sokoloff lays down the following general rules: (1) Typical retro-pharyngeal abscesses, situated entirely in the retro-pharyngeal space, should be opened by a sufficiently large incision through the mouth. (2) Such abscesses as cannot be reached from the fauces, on account of their deep situation, should be cut into externally, through the lateral aspect of the neck, as practised by St. Germain, Bokai, Burkhardt, etc. (3) The same procedure should be also employed in cases where the abscess is spreading towards the lateral surface of the neck, having passed under the external cervical aponeurosis outwards from the vascular bundle. (4) Traumatic phlegmon of the retro-pharyngeal cellular tissue and tubercular congestive abscesses must be always opened after the external method. (5) The latter prevents wounding the tongue, as well as the penetration of pus into the respiratory tracts. Having found ordinary pharyngotomies and scalpels inconvenient for emptying retro-pharyngeal abscesses, the author has invented an instrument of his own which represents a small-sized knife with a protecting sheath. The main disadvantage of an ordinary scalpel is said to consist in the impossibility of making a sufficiently free incision, the consequences being retention of pus and the disagreeable necessity of repeating the operation, and inflicting multiple wounds of the posterior pharyngeal wall.

#### NASO-PHARYNGEAL CATARRH A CAUSATIVE FACTOR IN GASTRIC CATARRH.

Dr. Louis Fischer<sup>4</sup> is of the opinion that gastritis in adults and children, is caused very frequently by the constant swallowing of catarrhal exudations of an acute pharyngitis. In speaking of the anatomical relationship he says that when we consider the anatomical position of the pharynx, situated above and the stomach below, it is easy to understand how all exudations from the pharynx, be they mucous, muco-purulent, muco-sanguinolent, or otherwise combined, can and usually do, gravitate toward the stomach, either by involuntary or voluntary deglutition, especially at night, in the same manner as the insensible swallowing of saliva is continually carried on.

Children show the picture remarkably. They cannot hawk and spit as adults, consequently all catarrhal exudations forming or lying in the pharynx, and interfering with the natural comforts of the child, tend to produce, through irritation, swallowing movements, and thus it is that large quantities of septic material are forced directly into the stomach, in this way causing an infection. In several children where stomach washing was resorted to, large quantities of catarrhal (usually muco-purulent) exudation was found, corresponding with the increase or decrease of existing catarrhal pharyngitis.

Dr. Fischer has observed numerous cases in which by attending and curing the pharyngitis the gastritis ceased.

#### LARYNGEAL COMPLICATIONS IN TYPHOID FEVER.<sup>5</sup>

In severe cases of enteric fever various throat complications have been described, but their connection

with the original disease has not been satisfactorily established. In *L'Union Médicale* of March 10, 1891, Professor Peter describes the case of a man who died of typhoid fever, and in whom the throat complications were well marked. In commenting on the case, he remarks that hyperæmia of the larynx is a common symptom of typhoid fever, being most marked on the aryteno-epiglottidean folds. Ulceration following this condition was first noticed by Louis, in 1828, who stated that if at a necropsy extensive ulceration of the larynx was found, and if tuberculosis could be excluded, typhoid-fever lesions should be sought for. Occasionally, when the laryngitis is intense, Eberth's bacilli are found in the glands around the larynx. An oedematous swelling often appears, and the inflammation may lead to suppuration, extensive ulceration, and even destruction of the cartilages.

Laryngitis, in connection with enteric fever, assumes two chief forms: the acute and the chronic. The first mentioned develops from the fifteenth to the twentieth day, at the time when the disease ought to be subsiding. Its onset is marked by local pain, difficulty in swallowing, and dyspnoea, chiefly affecting inspiration, expiration being perfectly easy. The difficulty of breathing gradually increases, generally requiring tracheotomy to be performed in order to prevent death by suffocation. Post-mortem, there is found sero-fibrinous, or purulent infiltration, with commencing destruction of the epiglottis and the arytenoid and cricoid cartilages. The more chronic form does not commence until convalescence has been well established, at least two months after the termination of the attack, and when the patient is apparently cured. The voice becomes hoarse, there is evident difficulty in speaking, and finally symptoms of oedema of the glottis appear. The prognosis is then very grave; according to Lestier, of ten cases which required tracheotomy, all proved fatal. Some German statistics show that of nineteen cases that required operation, seven only recovered. Even if a cure is effected, the condition is a very unsatisfactory one, as the canula has to remain in position for an indefinite period, and the cicatrices which form in the larynx often producing such constriction as to cause almost total obstruction.

In short, in all the parts affected by enteric fever, there is a tendency to ulceration, and this is particularly liable to occur in the larynx, and if such happens, the submucous tissue becomes infiltrated, and perichondritis follows in its turn. Finally, there is erosion of the cartilage; and, if the patient survives, there are premature ossification of the cartilages and necrosis of the epiglottis and of the arytenoid and cricoid cartilages. Sometimes a small portion of cartilage may be detached—a very dangerous occurrence, as it is very apt to fall into the trachea and cause alarming symptoms, and even death from suffocation. At other times the whole cricoid cartilage may become detached, and be ejected in the form of a sequestrum. The only treatment likely to be effectual is to apply counter-irritants, such as blisters, to the front of the neck.

#### INTUBATION OF THE LARYNX.<sup>6</sup>

A paper, by Dr. Dillon Brown, of New York, on the construction of O'Dwyer's tubes, read at the meeting of the American Pediatric Society, is published in

<sup>4</sup> Medical Record, June 13, 1891.

<sup>5</sup> Lancet, April 1, 1891.

<sup>6</sup> Supplement to the British Medical Journal, February 21, 1891.

the *Archives for Pediatrics* (January, 1891). The author stated that many of the tubes in use were badly constructed, and that the failure of the operation was often due to such defects. Minute instructions for the guidance of the surgical instrument maker were contained in the paper, but the desirability of having a good pattern to work by was also mentioned. Three sets of tubes were described — for children (six tubes), for adults (ten tubes, of which three only are required for acute stenosis), and for the treatment of foreign bodies or loose membrane (seven tubes). The first two sets are of the same pattern, and are made of brass heavily plated with gold. The tubes for foreign bodies or membrane are made of very thin German silver. These tubes are short (one and one-eighth inch), cylindrical, but tapering a little towards the lower end, and the head is smaller than in the ordinary tubes. The tube, it was stated, was intended to fill the larynx to its full subglottic capacity, and was held in position by the pressure. It was believed that any foreign body which could enter the larynx, provided it was not of a nature to swell by imbibition, might be expelled through such a tube. In the ordinary tubes an artificial epiglottis introduced fresh sources of danger, and was not necessary since experience showed that swallowing was not difficult if, during the act, the head were placed in such a position that the pharynx was lower than the larynx.

Dr. Brown added a table increasing the total number of cases treated by him to 350; he reported altogether 100 recoveries, or 28.5 per cent. It appears from the table that in his last 50 cases Dr. Brown had 13 recoveries, or 26 per cent., and that four of these cases were not suffering from diphtheria. Of the 37 cases that died, five only were not suffering from diphtheria. As to the danger of sudden asphyxia from pushing the membrane down in front of the tube, Dr. Brown stated that in over 600 cases in which intubation had been performed by himself or Dr. O'Dwyer, this accident had not occurred once.

## Reports of Societies.

### ASSOCIATION OF AMERICAN PHYSICIANS.

THE SIXTH ANNUAL MEETING, HELD IN WASHINGTON, SEPT. 22-25, 1891.

(Continued from No. 16, page 415.)

THIRD DAY. — THURSDAY.

### THE RELATIONS BETWEEN ARTERIAL DISEASE AND VISCERAL CHANGES.

DR. GEORGE L. PEARBODY, of New York, Referee:

The causes of arterio-sclerosis are varied, whether due to syphilis or not, we cannot always say. We look for the lesion in the blood-vessels, and in particular in the arteries. From an examination of the intima of the artery it cannot be said what is the cause, just as in phthisis we find well-marked sclerosis, not tubercular in nature. In the thickening of the walls of the arteries in Bright's disease, the cause of the fibrous growth has hitherto escaped detection. It is hard to find out which the cause and which the effect of the change in the kidneys and in the blood-vessels.

Dr. P. C. D. 's paper will appear in full in the next issue of the Journal.

After partial study, Thomas came to conclusions which we may in part accept. The interstitial inflammation in the kidney is the cause, not the effect, of the change in the arteries. The changes in the artery begin after birth. This change extends gradually. First, there is a slowing of the blood-current in the aorta; the circulation in the two umbilical arteries ceases at birth; the arteries become disproportionately large. The result is that the blood-current passes through it more slowly. The new growth in the intima tends to reduce the size of the artery, and this is due to the cessation of the circulation in the placenta. The same changes occur in arteries whose size is suddenly diminished by surgical procedure, ligature, etc. There is a lesion in the intima, the endothelium of the blood-vessel becomes affected, a dilatation takes place, a slowing of the blood-current, changes in the vasa vasorum, a thickening; the sensitive nerve-filaments in the arterial walls appreciate the change in the vasa vasorum. The tension of the arterial walls is the cause of the form taken by the growth under different circumstances. As soon as the blood current is settled, the changes stop. The change is a purely mechanical one. Diseased arteries give less blood to the organs than they require to have, and this goes on causing more and more change. We may have senile changes, changes in the arteries, veins, or capillaries, and these may occur in a great variety of conditions. It is seen with corresponding changes in the kidney, testicles, and other parts. Heredity, gout, rheumatism, functional arterial strain, and many other causes may be at hand.

The effects of these changes in the arteries may lead to an aneurism. The walls, being weakened, dilate, they are less elastic than normal. There is increased pressure, and the lumen of the vessel is increased too. At first, the intima of the artery is able to withstand the pressure, but later it cannot. This dilatation can be produced artificially in other vessels, but it cannot be done in healthy arteries. The time within which an aneurism can be produced while this change is going on, is supposed to be one year, and after that time the intima becomes so reinforced that the aneurism cannot be formed. This is the rule for each vessel, so that as changes occur, first in one vessel, and then in another, the danger of the formation of an aneurism in any one vessel would exist during one year after the vessel was affected; but as all the changes do not go on in all the vessels at the same time, the period of danger would be between thirty-five and forty-five years. The diagnosis of this trouble can also be made from an ophthalmoscopic examination. The carotid vessels are generally early affected. It is a common cause of the left ventricular hypertrophy, which is caused by the overtaxation of the muscular fibres of the heart, with a diminution of the elasticity of the arterial walls.

DR. W. T. COUNCILMAN, of Baltimore, Co-referee:

When we neglect the earlier publications which have appeared on this subject and which have chiefly referred to the histological details of the processes in the organs, the two most important publications are those of Gull and Sutton and of Thoma. Gull and Sutton describe, under the name of arterio-capillary fibrosis, a general disease, the chief lesions of which consist in the formation of hyaline or slightly striated connective tissue in the adventitia of the small arteries and capillaries. In the kidneys the process extends

from the adventitia of the vessels into the interstitial tissue, causing the parenchymatous elements to atrophy. There is also some formation of the same tissue in the intima of the vessels. Thoma, in a remarkable series of publications in Virchow's *Archiv*, in the last few years discusses the entire question of endarteritis and arterio-sclerosis, and endeavors to trace in the process the action of a common law. He starts out with the study of the lesions which take place in the aorta of the child after the closure of the umbilical arteries and the ductus Botalli. He finds that there is an endarteritis of the aorta limited to the portion between the ductus Botalli and the umbilical arteries. He has also studied the changes which take place in the arteries of an amputated stump, and he finds that whenever the vascular bed is too wide for the territory to be supplied, that there is an endarteritis set up which restores the calibre of the vessel to a normal relation. He divides arterio-sclerosis into three varieties, one the nodular endarteritis, another the diffused primary arterio-sclerosis, and the other the secondary arterio-sclerosis. In the first two of these there is a lesion of the media causing a dilatation, with a following formation of connective tissue which fills up the dilated portion and restores the artery to a normal calibre. In the nodular, only small areas of the vessel are affected, and in the diffused primary the entire aorta and larger arteries may be affected. The secondary arterio-sclerosis is due to dilatation of the aorta, which arises from an increase of blood-pressure due to peripheral resistance caused by changes in the minute arteries. It is this third variety of arterio-sclerosis in which we are most interested.

In the last two and a half years at the Johns Hopkins Hospital there have been forty-one cases of general arterio-sclerosis. These can be divided into two forms, the senile endarteritis and the diffused arterio-sclerosis. In the senile endarteritis there are changes in the aorta, which are chiefly degenerative and which are part and parcel of the senile changes in the body generally. The arteries are frequently converted into rigid calcareous tubes. There is no heart hypertrophy unless there are changes other than those in the arteries to account for it. In the fourteen cases of senile endarteritis which we have examined there was heart hypertrophy in seven cases. Of these, two cases were complicated with disease of the aortic valves and in five, the senile endarteritis was complicated with other changes to be described. The subjects of this are mostly men of advanced life. In the diffused arterio-sclerosis we have not been able to make the two divisions which Thoma has made into primary and secondary. The subjects of this are usually men in the prime of life, well nourished, muscular individuals. As a rule, there is no oedema; and when there is, it comes on in the last days of life and is due to chronic passive congestion arising from the dilated heart. The heart in many cases is enormously hypertrophied. In one case the heart weighed 850, and in another case 820 grammes. With the heart hypertrophy in the advanced cases there is also a great deal of dilatation leading to incompetence of the valves. The aorta and large arteries are thickened not only homogeneously, but there are scattered elevations over the surface and fissures in it. The arteries are also elongated, this being seen not only in the accentuation of normal curves but in the formation of curves where none exist. The kidneys and liver were more intimately studied

than any other organs, not only on account of the importance of the lesions in these, but on account of the facility which their tissues offer for the study of the smaller vessels. The kidneys were of normal size or slightly reduced. Frequently the changes were so slight that they would scarcely be noticed on a superficial macroscopic examination. The capsule in some cases stripped off easily, in others it adhered slightly and when stripped, small losses of substance were seen. In other cases there were deep depressions on the surface of the kidney, corresponding to more extensive losses of substance. On microscopic examination various degenerative changes were seen in the renal epithelium and there was a formation of fibrous tissue both in bands going down from the cortex and more diffusely over the entire organ. All of the small arteries were affected. The disease here consists chiefly in an enormous thickening of the intima, the thickening being due to the formation of a hyaline or slightly striated tissue containing relatively few cells, and various degenerative changes in the media and elastica. The muscular fibres of the media were atrophic, fatty, and frequently the entire media as such was gone, its place being supplied by a rather dense connective tissue. The glomeruli were also affected, the chief lesions being thickening and obliteration of the capillaries with the formation of connective tissue between them, and, coincident with the atrophy, an increase in the thickness of the capsule. The macroscopic appearance of the kidney may present little change but there is increased resistance of the tissue on cutting or tearing the organs.

The changes in the liver are but little marked to the naked eye. Here also there is an increased density and resistance to the tissue. The finger can be thrust into it with difficulty, and it is more difficult to break or tear the tissue. On microscopic examination the capillaries are little if at all dilated, the liver-cells are small and atrophic, and the capillary walls are greatly thickened. One of the most marked features is fatty degeneration of the stellate cells of Kupfer. The changes in the larger arteries and in the aorta are very similar to those in the smaller arteries. Here, also there are various degenerative lesions of the media and elastica with a thickening of the intima. In the brain and elsewhere there is evidence of diffused connective tissue formation leading to increased density. We do not think that it is necessary to assume, as Thoma has done, that this new formation of tissue in the intima is due entirely to a dilatation, but is due rather to the connective tissue formation which always follows a degeneration. The dilatation, it is probable, will also act in assisting this. As for the second variety of Thoma, it is not at all sure that increase of blood pressure in itself will lead to any dilatation and endarteritis of the arteries; on the contrary, we have examples enough in which, with an enormously hypertrophied heart, we have normal arteries. We would regard arterio-sclerosis as a general disease in which the primary lesions consist in fatty and various other degenerations of the media of all the arteries of the body, the changes in the tissue depending upon lack of nutrition, resulting from these arterial lesions and followed by diffused formation of connective tissue.

DR. WILLIAM M. ORD, of London, did not criticise the papers of Drs. Peabody and Councilman, which he characterized as most able and comprehensive; but he gave some of his own experience with certain forms of

arterial disease. . . . There is a question whether the changes in the arteries and capillaries are the result of renal disease or part of the cause of it, or are a part of a disease affecting the whole system, perhaps most characteristically seen in the kidneys on the one hand, and in the arteries on the other. For his part, long observation inclined him to think that it is not merely a disease of the arteries or kidneys, but a general disease affecting the whole system, and very closely associated with gout,—gout depending on injudicious feeding, to a large extent, in the way of both food and drink. He could recall at least twenty men, whom he had known in one of the suburbs of London, who ate heartily of meats, and washed them down with liberal libations of alcoholic beverages, but who never became drunk, who fell away in middle age with symptoms which began in more or less of a gouty fashion, and ended with distinct contracting granular kidney. Some years ago Dr. Ord asked the demonstrator of pathology at St. Thomas's Hospital, London, to examine the great-toe joints in a series of people, aged between forty and sixty, with regard to the presence in them of a deposit of urate of soda. In about 130 cases taken hap-hazard, deposit was found in seventeen cases. Of these seventeen, twelve had unmistakable contracting granular kidney, often very pronounced; and in the remaining five there were in all changes in the kidney of an allied nature. Not always was there only contracting granular kidney, but composite changes in which it was clear that arterial degeneration took a considerable part.

Referring to a case cited by Dr. Peabody, of a boy dying of cerebral hemorrhage, Dr. Ord said that as far as he was aware we do not get cerebral hemorrhage of large bulk in the young without aneurism, either milinary or larger. A case had come under his observation of a boy dying from cerebral hemorrhage. His brain was twice examined by others for aneurism, with negative results. Dr. Ord was satisfied that an aneurism must exist, and a third search revealed an aneurism, about the size of a pea, communicating by a slit-shaped orifice with the cyst containing the blood clot. Both with regard to a great deal of cerebral and pulmonary hemorrhage, we must refer still more and more to aneurism as a source of the bleeding.

Dr. W. T. GAIRDNER, of Glasgow, speaking on the subject of the relation of arterio-sclerosis to aneurism, thought that forces of a mechanical kind, acting upon the arterial coats from within, give the first impulse to local dilations and thus tend to the production of aneurism. Dissecting aneurism has in all probability some relation to strain of the inner coat of the artery; the peculiarity of dissecting aneurism being that the inner coat becomes severed and the blood is admitted to free communication with the middle coat, and instead of forming a pouching aneurism it dissects the fibres of the middle coat. A case was described of a young and athletic negro, who leaped down a distance of fifteen feet, receiving a shock which soon brought his life to a close. Examination showed a tear of half an inch or so in the inner coat of the aorta from which the blood had started a separation of the fibres of the middle coat to an inch or two, then there was a new rupture of the outer coat opening into the pericardium at a point two or three inches from the point of the internal rupture. This case illustrates a dissecting aneurism in the very act of its production in an artery not visibly diseased. If a strictly healthy ar-

tery torn in this way under strain may lead to dissecting aneurism, it seems likely that in arteries which have not undergone much degenerative disease, but in which the inner coat is brittle or gets accidentally ruptured, the result of strain may be, in certain cases, a dissecting aneurism; and if there is much softening of the middle coat and the strain is not such as to lead to a positive rent, the same kind of strain, which produced in the first instance rupture of the vessel, might probably result in a bulging of the middle and inner coats, and that bulging once produced might lead to agglutination of these coats so as to protect them against the dissecting process, but, on the other hand, to expose them still more to irregular dilatation, and that, gradually, by the force of the blood, such dilatation would become sacculated and enlarge into an aneurism.

Dr. Gairdner's pathological experience had not prepared him for the apparently precise statement of Dr. Peabody, that the period of degeneration, during which the liability to aneurismal protrusion is likely to be established for the first time, extends over about a year. But it may well be so, for it is a matter of daily experience that in the very advanced stages of arterio-sclerosis, when the greater arteries are not only degenerated throughout, but infiltrated with calcareous matter, aneurisms are relatively rare. It may therefore be taken as probable that atheromatous infiltrations pass in this way toward a kind of healing,—a healing which is not only incomplete but is fraught with new kinds of dangers to life.

To the statement of Dr. Peabody, that, in attacks of angina pectoris, there is a difference in the radial pulses, Dr. Gairdner took exception; for, as far as his reading and personal knowledge of the subject went, there was no such difference, unless the angina-like symptoms depend, as they may do, upon aneurism.

Referring to Dr. Ord's experience with gout, Dr. Gairdner said that the experience of London is like the experience of no other place in the world in regard to gout. In Scotland, there is not the same form of gout as in London, although gout is doubtless increasing there at the present time, due to the development of habits of self-indulgence in connection with indolence.

#### INTESTINAL PERFORATION IN TYPHOID FEVER,

by Dr. REGINALD H. FITZ, of Boston.<sup>2</sup>

This complication is found in about one per cent. of all cases of typhoid fever, and is the cause of death in something more than six per cent. of the fatal cases. It rarely occurs in children, and is twice as frequent in man as in woman. It is present in the small intestine in more than four-fifths of the cases, and usually proves fatal during the first week after its occurrence. It takes place in mild or severe cases, and its symptoms may be absent or latent, gradual or severe.

Differences of opinion concerning its prognosis have existed for many years, and are based upon a lack of agreement as to the value of the symptoms. Though these are often called characteristic they give evidence only of a peritonitis general or circumscribed. This may, in typhoid fever, result from a variety of causes, and fatal perforation may occur without any symptoms suggesting its presence.

Most cases of recovery from symptoms of perforation of the bowel in typhoid fever, are those in which an attack of appendicitis is closest simulated, while

<sup>2</sup> See page 336 of the Journal.

the great majority of the fatal cases are those in which other parts of the bowel than the appendix are perforated. It is probable that the appendix is more often inflamed and perforated in typhoid fever than has, hitherto, been suspected.

The prognosis of apparent perforation of the bowel, in typhoid fever, is to be regarded as the more favorable the more closely the symptoms and their course resemble those of an appendicitis.

In the treatment of this complication early laparotomy is reported to have been tried in ten cases, with but one successful result; while of twenty-seven cases of circumscribed peritonitis in typhoid fever, largely attributed to intestinal perforation, three recovered after incision, seventeen after resolution, and nine after the spontaneous discharge of pus.

It is recommended that immediate laparotomy be employed for the relief of suspected intestinal perforations in typhoid fever only in the milder cases of this disease. In all others evidence of a circumscribed peritonitis should be awaited, and may be expected in the course of a few days. Surgical relief of this condition should then be urged as soon as the patient's strength will warrant.

DR. DaCOSTA thought the paper of Dr. Fitz was of the thorough and lucid character which we always associate with the name of its author. With reference to the point made of early perforation and an operation for its relief, Dr. DaCOSTA related his own experience. One case was extremely valuable because it was operated upon within four or five hours after the perforation. The patient, a young man of nineteen, had typhoid of rather severe type. The fever terminated in the fourth week, and everything was supposed to be in complete convalescence. Ten days after this the patient was seized with violent pain in the right iliac fossa, and soon signs of collapse came on. The family physician sent for Dr. DaCOSTA, but even before his arrival an operation had been determined upon. An eminent surgeon, Dr. Martin, performed the operation. The result was worse than negative. He seemed to rally for a little time, did well apparently thirty-six hours, and then died. In a second case the operation was performed about thirty-six hours after the perforation, with like results. The intestinal lesions were found to be several inches above the ileo-cæcal valve. Dr. DaCOSTA would never sanction an operation in perforation unless a causal appendicitis could clearly be made out, or for the relief of a patient from a peritonitis.

ON THE RELATION OF DRINKING-WATER TO DISEASE,  
by DR. HENRY P. WALCOTT, of Cambridge, Mass.

The vast literature upon the subject of drinking-water and its influence upon human health contains but little that is of real value to the physician, in helping him to cure or prevent disease.

Chemical analysis has failed to distinctly indicate the waters which may produce disease; for of two waters, one capable of producing serious disease and the other not, the first may be found to contain less of suspicious substances than the second. Chemical examinations made when epidemics prevailed revealed undoubted pollutions; but, so far as chemistry was relied upon as a proof, the pollutions were often no greater during an epidemic of infectious diseases than they had been before it, and no less than they would be when the epidemic was past.

Improvements in the methods of determining both the kinds and the number of the minutest forms of organic life, and the proved connection of some of these forms with infectious diseases, have given to us more satisfactory means for the proof of the harmfulness of certain waters than chemical analysis has hitherto afforded.

There are many ways in which a water may produce disturbances in the human system. The human parasites which are known to occur in surface waters are numerous, and may enter the body fully developed or in the form of ova. They are easily found in the water by the use of the microscope, and can be readily removed by filtration or destroyed by the application of sufficient heat. Again, waters may contain substances which, either by quality, or by mere quantity only, disturb the system. The well-known action of some of the mineral contents of natural water may be cited. Bacteria found in water are for the most part harmless when taken into the human stomach, but there are a limited number of disease-producing bacteria associated with the harmless varieties, which have come from the excreta of the sick, which have gained access to bodies of water used as sources of supply. In our present lack of accurate knowledge, we may also assume that certain bacteria, which are not in the line of descent from those which have ever been present in the diseased human body, may, upon gaining entrance to it, become a cause of disease. As the senses of sight, smell, and taste offer us no protection against the waters that contain any of the now-known disease-producing bacteria, we must seek for safety the waters which are known to be unpolluted by sewage, or, if this be impracticable, waters which, though sometimes polluted, have been rendered harmless. Methods for the biological examination of waters have not yet been devised that are practically available for the purpose of protection.

As an instance which goes to show the connection of an infectious disease with the domestic use of river-water, the experience of Lowell and Lawrence, Mass., with typhoid fever was cited. Lawrence and Lowell are both situated upon, and derive their water-supply from the Merrimac River. The in-take of the Lawrence water-works is nine miles below Lowell. The Merrimac has always been regarded as a marked instance of the capacity of a large body of water moving rapidly to purify itself. There is nothing in the appearance and taste of the water to deter a community from its use, nor does the chemical analysis indicate a water too polluted for drinking. The average death-rate from typhoid fever, of all the cities of Massachusetts, for twelve years, from 1878-89, was 4.62 per 10,000; for the same period in Lowell, the rate was 7.63, and in Lawrence 8.33 per 10,000. The death-rates of Lowell and Lawrence from typhoid do not vary essentially from those of the State, as a whole, up to the month of September. From this month on, a condition of things exists in the two cities distinct from what is observed elsewhere in the State; that is to say, the deaths from typhoid fever continue to increase in number in Lowell until December, and in Lawrence till a still later date, whereas in the rest of the State the disease begins to decline in November. We find such a condition of things to exist as we should expect to find if a disease capable of being transmitted by the infected excreta of those sick with it had prevailed during the late summer and early

autumn, at some point on the river above Lowell. The infected discharges of the sick in Lowell would, with the sewage of the city, enter the river nine miles lower down, and would be taken into the water-supply of Lawrence, causing there a later outbreak of the same disease that had prevailed in Lowell. It is suggestive that the city of Haverhill, situated on the Merrimac nine miles below Lawrence, but not deriving its water-supply from this river, had a typhoid fever death-rate, in 1889, of only 3.33 per 10,000.

In the past year Lowell and Lawrence experienced an epidemic of typhoid fever of great severity. An apparently successful attempt was made to prove the existence of cases of typhoid fever at points on the river above Lowell, and to show that the discharges from the bowels of the sick had found immediate entrance to the river. In the months of August and September, several well-defined cases of the disease had occurred in people living along the course of Stony Brook, an affluent of the Merrimac, entering the river at a point about two and one half miles above the in-take of the Lowell water-works. Some of the sick, in the early stages of the disease, had made use of the privies which overhang the brook.

The temporal connection of these cases was such that, with the allowance of two weeks for the time occupied by the incubation and early stages of the disease up to the time of taking to bed, we find an apparently direct relation to the serious increase of the disease in Lowell in the latter part of October, 1890. The amount of infective matter did not at this time appear to be sufficient to pollute the river, to the same serious extent, at the in-take of the Lawrence water-works nine miles below Lowell. With the increase of the disease in Lowell there came the growing serious pollution of the river, and the people of Lawrence began, in turn, to suffer.

Dr. Walcott quoted many interesting facts about the water-supplies of the State of Massachusetts which have been ascertained as the results of the thorough physical, chemical and biological examinations being conducted under the supervision of the Massachusetts State Board of Health, and which will appear in the reports of the board.

#### PATHOLOGY OF PERNICIOUS ANEMIA,

by Drs. J. P. Crozer Griffith, and Charles W. Burr, of Philadelphia, Pa.

The subject of the various affections constituting forms of anemia is very obscure, but some system of classification is necessary for purposes of study. We offer a tabular scheme, according to which anemia is divided into the non cytogenic and the cytogenic forms. The second division contains such forms of anemia as chlorosis, leukemia and lymphatic anemia. The first division contains, among other subdivisions, the hemolytic varieties; and first among these stands pernicious anemia.

A number of cases have been published which would seem to show that no sharp lines of demarcation exist between many of the various forms of anemia. Among these are instances of apparent change of lymphatic anemia into leukemia, chlorosis and leukemia into pernicious anemia, etc. Yet there is, we think, good reason to believe that at least many varieties of anemia are totally distinct — certainly that chlorosis is to be sharply separated from pernicious anemia.

Various theories have been held regarding the pa-

thology of pernicious anemia. Apart from some which have found no general acceptance, the belief that it is a cytogenic disorder has been by far the most widely accepted theory. This was based on the hyperplastic alteration in the marrow of the long bones seen in this disorder. Later, however, doubts began to arise regarding the truth of this view, inasmuch as the same alteration was at times found in anemias of other forms, and could be produced in animals by bleeding them. Authorities began to regard the marrow-change in pernicious anemia as secondary simply. The same remark applies to the alteration in the shape of the red blood corpuscles. A second view, held by several, is that excessive hemolysis occurs in pernicious anemia, but that this is due to an imperfect cytogenesis, which causes the corpuscles to break down very readily. A third view is that brought into prominence by Hunter: that pernicious anemia is a hemolytic disorder, entirely independent of any defect in cytogenesis. This latter theory has been corroborated by later observers, and is, moreover, in accord with the earlier researches of Quincke, Peters and others. Hunter based his conclusions on the great increase and characteristic arrangement of an iron-holding pigment in the liver in pernicious anemia; on the character of the urine, indicating excessive blood-destruction; and on the fact that by the administration to animals of a certain hemolytic agent (toluyldiamine), the deposition of iron in the liver could be produced.

We have examined the liver in three cases of pernicious anemia. The sections were treated with a solution of potassium ferrocyanide, and then with a dilute solution of hydrochloric acid. The Prussian blue reaction was produced in the granular matter in the liver, the remains of the degenerated blood-cells. A very great increase in the amount of this iron pigment was visible in all these cases. The dark-blue granular matter was deposited abundantly in the hepatic cells of the outer and middle zones; the cells of the inner zone of the lobules containing but little or none. A yellowish pigment, unaffected by the reagents, was present to some extent in the cells in the neighborhood of the central vein.

As check observations, we have examined a large number of livers from different disorders. In none of these was there iron present in an amount at all comparable with that seen in pernicious anemia. In most instances iron was entirely or nearly absent. To a few of these cases some brief remarks must be devoted.

A case of fibrous cancer of the liver, stained with carmine, exhibited large yellowish patches irregularly situated, partly in the cells and partly in the fibrous tissue. Treated with the ferrocyanide, these patches became blue. On the other hand, a case of emphysema and dilated heart exhibited considerable yellow pigment in the liver, which did not react to the ferrie test. Still another case, one of pernicious malaria, exhibited much black pigment in the liver, and this did not react with the ferrocyanide.

These cases, as well as those of pernicious anemia, prove that there are various sorts of pigment in the liver, some of which give the reactions of iron and others not.

A case of infectious hemoglobinemia in the newly-born exhibited no iron in the liver, and only a slight blue tingeing of the tubules of the kidney, but no actual deposit of pigment there. In one of the cases

of pernicious anæmia a decided deposit of granular blue pigment was present in the cells of the convoluted tubules. It therefore appears, that in systemic hæmoglobinæmia, as illustrated by pernicious malaria and infectious hæmoglobinæmia, iron is not deposited in the hepatic or renal cells, while in portal hæmoglobinæmia this deposition does take place. The reason for the difference does not appear clear.

The liver from a case of leukaemia and that from one of lymphatic anæmia exhibited no noteworthy increase of iron. There was, therefore, no analogy in this respect between these two cytogenic anæmias and pernicious anæmia.

The liver was examined in several cases of Bright's disease and of phthisis, and no iron found. It was also examined with a similar result in a case of cancer that exhibited great anæmia and cachexia during life.

In conclusion, we feel justified in accepting the theory, that in pernicious anæmia there occurs a deposition of iron in the liver unlike that seen in any other disease; and that, as a deduction from this and other facts, pernicious anæmia is a form of hæmolytic, a non-cytogenic anæmia. In a broad sense, the disease may be said not to be a unity, since different poisons might produce the same destruction of blood. Toluylendiamine, given by Hunter to animals, produced the same alteration in the liver. Pyrodine has rapidly brought about excessive anæmia in man through its hæmolytic action. The instances of what seemed to be pernicious anæmia due to bothriocéphalus latus, to atrophy of the gastric mucous membrane, and to decomposition of food in the stomach (case of Meyer), were probably the result of absorption of some hæmolytic poison. There is, however, no reason on account of this to consider pernicious anæmia as not an entity but as simply a symptomatic condition, because these affections may exist without the symptoms of the blood disorder. It is rather a distinct and superadded disease, which may arise whenever some certain poison is present and is absorbed, and which may rarely complicate any other affection.

As already stated, no absolute objection can be made against refusing to pernicious anæmia the title of an independent disease on the ground that more than one toxic agent may cause symptoms very similar to it. Besides certain ptomaines, it is probable that pyrodin and certain other antipyretics and other drugs capable of destroying blood may produce the characteristic symptoms. It seems better, however, to regard all these cases, including the anæmia seen in atrophy of the gastric mucous membrane and accompanying bothriocéphalus latus, as other and different forms of hæmolytic anæmia. It would then be a just conclusion to regard pernicious anæmia, in the ordinary sense of the term, as a truly independent affection, which may be defined as an extreme and increasing anæmia, without marked loss of flesh, not directly secondary to any anatomical lesion or the presence of any parasite, but due, as Hunter suggests, to the entrance into the portal circulation from the intestines of some certain hæmolytic agent whose origin is unknown, but which is probably of the nature of a ptomaine, perhaps produced by a micro-organism.

ON CHANGES IN THE RED BLOOD CORPUSCLES IN THE PERNICIOUS ANÆMIA OF TEXAS CATTLE FEVER,

by DR. THEOBALD SMITH, of Washington.

When a series of preparations of blood from cases

of progressive anæmia in this disease are fixed according to Ehrlich's method, stained in alkaline methylene blue, and decolorized for one or two seconds in a three-tenths to five-tenths per cent. solution of acetic acid, certain peculiar conditions of the corpuscles may be noted. When the number has fallen slightly below three million, a small percentage appear with a variable number of stained particles disseminated uniformly through the corpuscle. In some cells these particles are relatively large, many attain a diameter of 0.5  $\mu$ . and then appear strikingly like micrococci, if it were not for a certain variability in size. Each corpuscle may contain from five to twenty or more of these bodies. To those who for the first time examine a stained film of such blood, they are quite puzzling. In the more crowded areas of the film, groups of coccus like bodies appear everywhere, each group representing the disc of some enlarged corpuscle, the outlines of which are, as a rule, not distinct in such situations. As the number of cells continues to fall, corpuscles appear which are beset with an increasing number of stained particles, diminishing in size until forms appear, the disc of which seems covered with a precipitate of exceedingly minute stained points. Not all the particles with recognizable form are round, coccus-like, but some are angular and some appear like very short rods. As a rule, the smallest particles are associated with the more advanced stages of anæmia, although cells with the granules of various sizes are found together. When the number of corpuscles has descended to between one and a half and two millions, a still farther modification appears. Many of the large corpuscles now retain a uniform and pronounced bluish color after staining. Such corpuscles are usually somewhat folded owing to their thinness. The edges are not sharply defined, and within the disc is usually a paler circular or elongated spot from 2.5 to 3  $\mu$ . in diameter. The stain is not resolved into points by high powers (1,500). Curiously enough, corpuscles containing stained granules have not been detected in preparations from the parenchyma of spleen, liver and kidneys. They are evidently confined to the circulating blood. Diffusely stained cells are not so restricted, but may be observed in the organs as well.

In the blood containing from one to two million corpuscles, nucleated red corpuscles or hæmatoblasts are present. They increase in number as the whole number of corpuscles diminish. Thus in blood containing two millions, they are detected with some difficulty. When the number has fallen to one million, about five per cent. are present. In several instances opportunity was afforded of observing the distribution of hæmatoblasts. In such cases they are equally abundant in the circulating blood, in the spleen, the liver and the kidneys. The spleen thus did not appear to have undertaken any blood-forming functions.

The order in which these different kinds of corpuscles appear in the circulation, as well as the particular stage during which each kind makes its appearance, is, as might be expected, not always as described above, although the description given applies to the great majority of cases examined. In those animals in which the destruction goes on very rapidly, fully two thirds of all corpuscles may have been destroyed before any of the modifications appear, and in most acute fatal cases death ensues before they are observed at all. It is only in the more chronic milder cases that these modifications are best studied. Their disap-

pearance when recovery begins is in the inverse order of their appearance and goes on quite rapidly.

That these morphological variations are due to the anæmia and not to any other cause, may be demonstrated by practising venesection on healthy animals. They were called forth both in a cow and in a lamb, by artificially reducing the number of red corpuscles by blood-letting.

The paper further discusses the nature of these modified corpuscles, and Dr. Smith adopts the theory of their embryonic or transitional character. The observations of Erb, Lowit, Howell, Ehrlich, and Gabritschewsky are briefly referred to. The two last mentioned authors seem to have observed the same modifications in human-blood corpuscles. While Ehrlich regarded them as undergoing a coagulation-necrosis, Gabritschewsky interpreted them as corpuscles whose development had been arrested.

In conclusion, attention is called to the clinical value of recognizing immature corpuscles in the circulation.

Dr. WELCH: Dr. Smith's paper illustrates the unity of medicine. As Virchow many years ago said, the diseases of animals and those of man are of equal scientific interest, the only difference being in the dignity of the subject of the disease.

Dr. Smith's descriptions of changes in the red-blood corpuscles in Texas cattle fever are of especial interest, as similar changes occur in certain forms of anæmia in human beings. His interpretation of these changes as all phases in one process, is possibly open to question, at least it is well to consider whether there may not be another interpretation. I have been in the habit of regarding the red corpuscles which stain diffusely—the forms first described by Ehrlich—as representing one form, not of degenerating but of developing corpuscles; the form with a small number of deeply stained, often irregular particles as a red corpuscle containing nuclear fragments; and the small regular granulations, scattered uniformly in large number through the corpuscle, as specific granulations in Altmann's sense. Dr. Smith's view that all of these forms belong together, and are transitional one to another, is interesting. He may have found in the blood of cattle affected with Texas fever, an object which will solve several important problems in the physiology and pathology of the blood.

(To be continued.)

#### AMERICAN LARYNGOLOGICAL ASSOCIATION.

The Thirtieth Annual Meeting of this Association was held at Washington, D. C., as a part of the Second Triennial Congress of American Physicians and Surgeons, September 22d to 24th inclusive.

##### THE ANNUAL ADDRESS,

delivered by the President, Dr. WM. C. GLASGOW, briefly reviewed the development of laryngology since the Association had been organized, and congratulated the members upon the many valuable contributions to be found in its proceedings, and upon the growing interest in the progress of this special department of medical science now shown in the general profession. The death of Dr. Egbert Carroll Morgan, of Washington, ex-President of this Association, and also of Homer A. Johnson, of Chicago, were noted, and appropriate action taken.

The Association increased its limit of membership from fifty to seventy-five, and elected Dr. J. H. Bryan, of Washington, a fellow.

The library of the Association was, on recommendation of the Council, directed to be deposited in the National Medical Library of the Surgeon-General's office, Washington.

The officers for the year 1891-92 were chosen as follows: President, Dr. S. W. Langmaid, of Boston; first Vice-president, Dr. Morris J. Asch, of New York; second Vice-president, Dr. S. Johnston, of Baltimore; Secretary and Treasurer, Dr. Chas. H. Knight, of New York; Librarian, Dr. Thos. H. French, of Brooklyn; Member of Council, Dr. Wm. C. Glasgow, of St. Louis.

Boston was selected as the next place of meeting. The date is to be named by the Council.

The annual dinner of the Association at the Hotel Arno, September 23d in the evening, was a social feature which was much enjoyed by the fellows and invited guests, although the unusual warmth of the weather was not conducive to extensive gastronomic effort.

##### A CASE OF FOREIGN BODY IN THE TRACHEA,

was reported by the President, Dr. GLASGOW.

A toy balloon had been inhaled by a colored child, about eight years of age, two hours before she was brought to the polyclinic; nothing was revealed by laryngoscopic examination, but attacks of aphonia and dyspnoea required the performance of tracheotomy. On the fifth day, the rubber balloon was found at the bottom of the tube and withdrawn, and subsequently the wooden whistle was pushed through the larynx and removed by the mouth. The child recovered. The inability to detect the foreign body by laryngoscopy was attributed to the wooden portion being enveloped in the rubber, which was so nearly the color of the mucous membrane that it could not be distinguished from it. There was only partial obstruction to respiration, except when the air got under the balloon and lifted it up into the trachea, when the attack subsided it fell back into the left bronchus, and the attack ceased.

##### A CASE OF THYROTOMY IN A CHILD EIGHTEEN MONTHS OLD,

was reported by Dr. CLINTON WAGNER, of New York.

The patient, from exposure and neglect, had suffered for several months with chronic laryngitis with persistent hoarseness. It subsequently developed spasmodic attacks of dyspnoea for which Dr. Wagner performed tracheotomy. Two weeks later he did a thyrotomy and removed a small papilloma from the left vocal band, near its posterior extremity. The patient immediately was relieved of its symptoms and made a good recovery after the operation, but perished several months later from the gripe, which was then prevailing. The reporter considered the case a success and wished to add it to three cases he had previously published. He had performed the operation ten times; six were fatal, though death was not caused directly by the operation. He said that he approved of thyrotomy for the removal of laryngeal obstruction from foreign body or benign growth, but considered it of doubtful propriety in malignant disease, except as a palliative where the obstruction is too great, or in

those cases where it is possible to entirely remove the diseased portion. In tuberculosis of the larynx, he pronounced it unjustifiable except as a palliative in great emergency.

Dr. MULLALL advocated the removal of papillomata from the vocal chords by the use of the index finger-nail, and referred to several cases treated in this way.

The use of anesthetics was discussed, and generally discontinued in laryngeal obstruction.

Dr. WAGNER declared that, in children under three years of age, removal of papillomata by the mouth is impracticable and thyrotony the only resource.

#### THE TONSIL IN HEALTH AND DISEASE,

was the subject of Dr. HARRISON ALLEN's communication.

He reviewed the structure of the tonsils, and showed that the openings usually called follicles are channels or crypts from which diverticula extend; these are lined with mucous membrane, in which are closed follicles, analogous to the agminated glands of the small intestine. In treating tonsil abscess, he preferred a small incision with subsequent antiseptic applications and free drainage. In obstruction of the crypts, he advocated careful opening and expression of contents followed by astringent injections. He strongly objected to amputation, or transverse section of the tonsils, on account of their complex structure. Experience had shown him that cases of enlarged tonsils are usually accompanied by disease in the nasopharynx, and, if the hypertrophied adenoid tissue in this situation be removed or properly treated, the enlargement of the tonsils disappears.

Dr. WRIGHT had found the reverse to be true, that if the enlarged tonsils are reduced in size, the adenoid growths in the nasopharynx get well. He thought that the enlarged tonsils dam up the secretions and thus lead to pharyngeal disease.

#### THE TROUBLESOME SYMPTOMS CAUSED BY ENLARGEMENT OF THE EPIGLOTTIS AND THE ADVISABILITY OF REDUCING THE SIZE OF THE CARTILAGE BY OPERATIVE MEASURES,

was the title of a paper by Dr. C. C. RICE, of New York.

He recognized an actual and permanent increase of size in the cartilage of the epiglottis, it might be congenital or the result of disease, or abuse of tobacco, alcohol, or from local injuries. Enlargement of the lingual tonsil is an active cause. The symptoms are constant tickling or fulness in the throat, pain, cough, etc. He advocated the removal of the excess of tissue by scissors or cutting forceps. In doing the operation, he makes a preliminary application of cocaine to the throat and epiglottis before administering chloroform. He claims special advantages in this operation, for this combination of local and general anesthesia.

The appointed discussion on

#### THE RESULT OF TREATMENT OF THE UPPER AIR-PASSAGES IN PRODUCING PERMANENT RELIEF IN ASTHMA

was opened by Dr. F. H. BOSWORTH, of New York, and generally participated in. The opinion was expressed by the respondent that, while all cases of nasal disorder do not have asthma, in a certain proportion of such cases this relation exists and most of these are

benefited or even cured of asthma by restoring the integrity of the air-passages. He recognized three factors in every case of asthma: (1) a peculiar, nervous state or susceptibility; (2) an external, exciting cause; and (3) a local point of exalted sensitiveness, which is frequently found in the nose. Since his last communication he had seen 85 cases, of which 42 were cured and remained free from the attacks for a year after receiving local treatment, 32 were improved, two were not benefited, and in the remainder no report could be obtained.

#### NASAL PAPILLOMATA,

was the title of a communication by JONATHAN WRIGHT, of Brooklyn, in which a review was given of the literature of the subject and of the microscopic examinations made. It was shown that Hoffmann and others who consider the disorder a common one had based their writings upon inexact diagnosis. The lecturer had found the condition very rare, and occurring, as a rule, on the septum at the muco-cutaneous junction. He advocated the abandonment of the term papilloma and suggested "papillomatous fibroma" as a better designation. It should not be mistaken for masses of glandular hyperplasia occurring in the course of chronic rhinitis, and appearing especially upon the lower turbinated bone.

#### THE STUDY OF A CASE OF NASAL TUBERCULOSIS,

was the title of a very interesting report of a monkey with catarrhal discharge from the nasal passages, in which numerous tubercle bacilli were found. Under treatment, chlorine-water locally, and good care, the patient improved, the discharge was reduced, and the bacilli became very few. The monkey was subsequently killed and no tubercular lesions found in the lungs or other viscera, and no local signs in the upper air-tracts could be discovered. It was regarded as a case of local tuberculosis, the seat of bacterial growth being in some fold of mucous membrane, which furnished a suitable culture-ground.

#### CYST OF THE MIDDLE TURBINATED BONE.

A case of this kind was reported by Dr. C. H. KNIGHT, with diagrams and specimen. The cyst has a thin bony wall, and is only seen at the end of the middle turbinated bone, and may occlude the nostril. These cases are not very rare; none of those he had seen were under twenty years of age. The theory of formation of these cysts that the lecturer preferred, was not that which attributes them to rarefying osteitis, but that which regards them as originally a projection of the edge of the turbinated bone, that grows and curls over upon itself until it meets the base where it unites with the bone, thus forming a cyst lined with epithelium. It subsequently grows in bulk, and the secretions may be mucoid or muco-purulent.

#### VARIOUS FORMS OF DISEASE OF THE ETHMOID CELLS,

was the subject of a systematic paper by F. H. BOSWORTH of New York. During last year he had seen 27 cases of disease affecting the ethmoid cells. He proposed a clinical division of these cases, into five varieties, as follows: (1) Extra cellular myxomatous degeneration, without purulent discharge; (2) extra-cellular myxomatous degeneration, with purulent discharge; (3) purulent ethmoiditis, with nasal polypi (often with antral disease); (4) intra-cellular, myx-

omatous degeneration, without purulent discharge; (5) intra-cellular, myxomatous degeneration, with polyp and purulent discharge.

The lecturer did not like the term of necrosing ethmoiditis, as used by Woakes, and considered it a hobby. In treatment he advised careful search for the site of disease and removal of the affected area with the curette or probe. In the general discussion which followed, the points made by the lecturer were appreciated and approved.

#### THE SYMPTOMS AND PATHOLOGICAL CHANGES IN THE UPPER AIR-PASSAGES IN INFLUENZA.

The appointed discussion on this subject was opened in masterly style by DR. J. SOLIS COHEN. The principal changes noted were a lymphoid infiltration of the soft tissues, with its consequences, such as edema, etc. The disease affects both the lymph-tracts and blood-vessels. He noted one interesting case of an old gentleman with epithelioma of the palate, in which the malignant disease sloughed out and a perfect cure resulted, after an attack of grippé; and another case in which improvement resulted in tuberculosis of the larynx, occurring in an old lady. The influence of an intercurrent acute infection like influenza or erysipelas upon the course of malignant disease or tuberculosis is worthy of study.

#### USEFUL DEDUCTIONS DERIVED FROM THE STUDY OF A CASE OF CICATRICIAL CONTRACTION OF THE LARYNX POSSESSING UNUSUAL CLINICAL FEATURES, WITH EXHIBITION OF SPECIMEN,

was the title of a paper read by DR. W. C. JARVIS, of New York. It was the result of extensive syphilitic ulceration, and nearly occluded the upper portion of the larynx. The patient had frequent attacks of dyspnoea, but refused tracheotomy, and perished of suffocation.

DR. MORRIS J. ASCH, of New York, read a report of a

#### CASE OF INTRINSIC EPITHELIOMA OF THE LARYNX,

in which, after a preliminary tracheotomy, the diseased portion was extirpated. The patient subsequently died with la grippé.

#### THE LARYNGO-TRACHEAL NEOPLASMS OF TUBERCULOSIS,

was the subject of a communication by DR. JOHN N. MACKENZIE, of Baltimore.

THE RADICAL TREATMENT OF NASAL MYXOMATA, was advocated in a paper by W. E. CASSELBERRY, of Chicago. He advised removal of the base of the growth, including bone, and the use of the galvanocautery to prevent recurrence. Too great interference was deprecated.

#### THE SURGICAL TREATMENT OF TUBERCULAR LARYNGITIS,

by DR. BRYSON DELAVAN, of New York, was read by title.

#### THE RELATION OF DISTURBANCES OF THE MUCOUS MEMBRANE OF THE UPPER AIR-PASSAGES TO CONSTITUTIONAL CONDITIONS.

The concluding discussion on this subject was opened by DR. BARTLEY ROBINSON; and a spirited and interesting debate followed.

## THE BOSTON Medical and Surgical Journal.

THURSDAY, OCTOBER 22, 1891.

*A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.*

**SUBSCRIPTION TERMS:** \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

*All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.*

*All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.*

*Remittances should be made by money-order, draft or registered letter, payable to*

DAMRELL & UPHAM,  
283 WASHINGTON STREET, BOSTON, MASS.

#### VIRCHOW'S SEVENTIETH BIRTHDAY.

PERHAPS in no profession or occupation at the present day, except in medicine, does there exist any one man so pre-eminent that its followers, each and all, would delight in recognizing him as the Master. The physicians throughout the civilized world universally acknowledge that to Rudolf Virchow belongs this title. During the past week two hemispheres have joined in thought, word and deed in celebrating his praise. There seems to have been scarcely any limit to the honors which have been showered upon him in grateful recognition of his efforts for the benefit of humanity. It is especially fitting that the President and medical professors of the Johns Hopkins University, the centre of scientific medicine in this country, should have held a memorial meeting in his honor, and it is with pleasure and thorough sympathy that we place Professor Osler's address before our readers.

Twenty years ago Virchow seemed to us as old as to-day, and to-day he seems as young as twenty years ago. He is certainly one of those exceptionally gifted mortals who, like the gods of old, is always in his prime. We forget, for the moment, that his greatest and most incisive contributions to medical progress were made before he was fifty years old. What he then accomplished was so thorough and so suggestive that it seems almost as if nothing had since been done except to confirm and extend what he then discovered.

Thirty years ago he gave us the cellular pathology, and although bacteriology has since budded and blossomed and became fruitful without his direct aid, its further progress is becoming more and more dependent upon the study of the cells whose importance he so thoroughly realized and whose changes he so keenly followed. He has been, and is, the director and controller of medical progress. Then, by his untiring industry and genius for generalization; now, by his example, incitement and critical wisdom.

How many sided is this great man, appears in Professor Osler's remarks. He has undertaken nothing which has not profited from his labors. A citizen

of whom Berlin is proud, a patriot to whom Germany is much indebted, a physician and man of science whose country is an appreciative world.

What more striking illustration of the fickleness of fortune and the irony of fate than Virchow and Bismarck on the 13th of October, 1891. The former laden, almost overwhelmed, with the gratitude of the world, the latter deprived of honors, his existence barely recognized by the country he unified. The memory of the one will live without blot or blemish, that of the other, though perhaps equally lasting, may be found seamed and scarred by the wounds and blows he inflicted, which posterity may find to have been largely unnecessary.

#### THE INCREASING IMPORTANCE OF BACTERIOLOGY IN ITS RELATION TO INTERNAL PATHOLOGY.

A PERSON ignorant of the progress which is being made in medicine might obtain a fairly good idea of the growing importance of bacteriology in internal pathology by contrasting standard works published twenty years ago with treatises of to-day. We have, for instance, before us editions of the following textbooks bearing date 1871: Niemeyer's "Text-Book of Practical Medicine," Wagner's "General Pathology," Jaccoud's "Traité de Pathologie Interne." In these works one might look in vain for any special chapter devoted to bacteriology, or for any adequate recognition of the relation thereof to etiology. Bacteriology was then only in its embryonic stage. Contrast this with the importance now assigned to this subject in standard treatises. The last edition of Hallepeau's "General Pathology," a book of 840 pages, published in 1890, devotes 200 pages under the head of Etiology, to "Animal and Vegetable Parasites," of which the larger part is concerned with "Infectious Bacteria." And now comes the first volume of the very latest "Treatise on Medicine," published under the direction of Charcot, Bouchard and Bressand.<sup>1</sup> This large book of a thousand pages begins with a long introduction by Charcot (Part I). "On General Infectious Pathology"; two hundred and forty pages are devoted to this one etiological subject, and may be regarded as quite a complete treatise on microbiology, in which the principal acquisitions of the last decade or two are grouped in a striking manner. We cannot forbear calling particular attention to the masterly manner in which the following topics are treated in successive chapters: "Microbial Associations—Mixed, Secondary Infections"; "The Microbial Secretions from the Point of View of their Physiological Actions"; "On Immunity"; "On Vaccines."

The advances of the past seventeen years will be recognized when this introduction is contrasted with that of Liebermeister, in the first volume of Zeimssen's Cyclopædia. The latter introduction comprises only thirty-two pages; and while containing much that time

has sanctioned and confirmed, the general classification of Liebermeister has proved to be inadequate, and has been abandoned. The word *miasm*, for example, has been found to comprehend the most diverse morbid agents: the hæmatozoa of marsh-poison, the deleterious gases engendered by saprophyte bacteria in cesspools and privies, and the poison contained in the expired air. Hence it has been seriously proposed to expunge this word from medical nomenclature.<sup>2</sup> Nor does the term *miasmatic contagions*, as applied to typhoid fever and cholera, find much justification in fact; the typhoid bacillus and the comma bacillus are the same contagion in the organism and out of it, only, if we may believe Wood, Pettenkofer and Hueppe, these bacteria may in some circumstances develop in certain external media, an extraordinary vitality and virulence.<sup>3</sup> With regard to the typhoid bacillus, it is true that drinking-water is generally the vehicle by which it obtains entrance into the human organism; it is equally true that water is but an indifferent medium of culture (though the bacillus may long preserve its vitality in water and even in ice), and that there are observations which indicate the communication of the disease (in ten per cent. of the cases, according to Professor Brouardel) by the air of respiration; and the presence of the specific bacilli in the dust of rooms which have been occupied by typhoid patients has been affirmed by Tryde and Salmøsen, by Utpadel and Birsch-Hirscheid.

Among the recent additions to medical bacteriology may be mentioned: (1) The relationship of angiocholitis to bacilli—the researches of Bouchard, Charrin, Roger, Dupré and others, have shown that angiocholitis with the resulting biliary abscess or hypertrophic cirrhosis is an infectious disease. (2) The determination of the infectious nature of certain acute enterites—the *bacterium coli commune*, the *bacterium lactis aerogenes*, the *bacterium aceti*, the *bacillus of Lesage*, are those to which the principal morbid agency has been assigned. (3) The identification of surgical septicæmia with puerperal septicæmia, and, as far as causation is concerned, with erysipelas, lymphangitis, acute abscess, etc., certain round micrococci being common to them all, and being capable, under proper conditions, of engendering any or all of these affections. (4) The wide range of morbidity attributable to the pneumococcus of Fräukel, which has been held to have not merely a primary part in croupous pneumonia, but also to be mainly responsible for much of the pleurisy, endocarditis, meningitis, otitis, etc., witnessed in connection with pneumonia and influenza. (5) It seems to be agreed among the microbiologists that most of the microbes which cause broncho-pneumonia, bronchitis, infectious laryngitis, etc., are, when we rule out the agents of syphilis, diphtheria, tuberculosis and glanders, such as are met with in ordinary pleurisy *à frigore*, that is, parasites of little specificity, which inhabit normally our cavities in communication with the outer air. It has, for instance, been stated that purulent pleurisy is

<sup>1</sup> Traité de Médecine, Tome I, par MM. Charrin, Legendre, Roger, Chantemesse, Feraud Vidal. Paris: G. Masson, 1891.

<sup>2</sup> Vide Hallepeau: Pathologie Generale, third edition, p. 173.

<sup>3</sup> Vidal: Asiatic Cholera, art., Bacteriology.

dependent on various bacteria, pneumococci, staphylococci, streptococci, etc.

It is needless to dwell again on the work which has recently been undertaken relative to the mechanism of immunity, to the bacterial secretions and their rôle in the symptomatology of the disease, and to that important rôle in morbid processes now assigned to associations of microbes. Nor need one more than allude to the increasing list of harmless microbes which are supposed to become virulent only under certain pathological conditions. Enough has been said to indicate the extent of the investigations in bacterial pathology. The basic facts are now indisputable, and nothing can stay progress in this department; so rapid, in fact, are the changes that text-books and treatises on medicine which three or four years ago were considered "up with the times" already begin to have the mould of age upon them, and need revision and supplementing.

The authors of the new French "Treatise on Medicine" realize this fact, and while demurring a little to the statement sometimes made in the way of reproach, that "pathology undergoes renewal every twenty years," they yet point with pride to the fact that during the last twenty years there has been a renaissance of surprising richness, "which has transformed not only the methods, but the very matter of medical teaching."

#### MEDICAL NOTES.

**INFLUENZA.**— Outbreaks of influenza are reported from Russia, from England and from Paris.

**A BIOGRAPHICAL SKETCH OF PROFESSOR VIRCHOW,** by Dr. W. Becher, is soon to be published in Berlin.

**FAMINE IN RUSSIA.**— It is estimated that fourteen million persons in Russia are in need of help on account of the famine. Scoury and typhus fever are raging in the afflicted districts.

**A PRIZE FOR AN ESSAY ON DEMOGRAPHY.**— At the recent Congress of Hygiene and Demography it was announced that Dr. Körösi had offered a prize of 1,500 francs for the best work on the subject of demography and its progress in the chief countries of Europe and the United States. Essays, which must be written in English, German, French or Italian, must be sent by January 1, 1894, to the Permanent Committee of the Congress. The name of the author is to be sent with the essay, but in a sealed envelope. The paper will be examined by an international committee of five, elected by the permanent committee. The prize will be awarded at the next meeting of the Congress at Budapest.

**PAN-AMERICAN MEDICAL CONGRESS.**— The Committee on Permanent Organization, appointed at the last meeting of the American Medical Association, met last week in St. Louis, Dr. C. A. L. Reed presiding. The Congress is to meet in Washington on the first

Tuesday in October, 1893. Officers were elected as follows: President, William Pepper, M.D., of Philadelphia; Secretary-General, Charles A. L. Reed, M.D., of Cincinnati; Member of International Committee, A. Van der Veer, M.D., of Albany; Treasurer, A. M. Owen, M.D., of Indiana. Trustees and Chairmen of Medical Sections were also elected. The selection of the Vice-presidents, one from each State and Territory, was left for the entire Committee in Detroit, next June, in connection with the meeting of the American Medical Association. The selection of Secretaries for the Medical Sections was left to a sub-committee. The name "Intercontinental American Medical Congress" was dropped, and the name "Pan-American Medical Congress" substituted. It was decided that the regulations governing the Congress be printed in the English, Spanish and French languages. Each section is to have an English-speaking, and a Spanish-speaking secretary. A number of communications were read from physicians of Rio Janeiro, Havana, City of Mexico and from the States of Venezuela, Porto Rico and San Salvador, assuring the committee of the hearty co-operation of the medical fraternity in those countries.

**REPORT OF THE SURGEON-GENERAL OF THE ARMY.**— In his annual report Surgeon-General Sutherland shows that while the number of sick reports was larger than during the previous year, the number of men constantly sick — 42.71 per 1,000 — compares favorably with 44.12 in the previous year. The cases of treatment of alcoholism numbered 40.73 per 1,000 for the army as against 41.43 in 1889, and 56.68 the average during the previous decade, and in this connection the surgeon-general notes with satisfaction that so many of the larger posts are at the lower end of the list. A great improvement in the diet of the men has been made within the past year. The complaints concerning clothing were not so numerous as heretofore. Treating in detail the subjects of alcoholism the report says, that drunkenness is on the decrease. The colored soldier is seldom on the sick-list from this cause. Every medical officer who refers to the canteen system approves of it, with the exception of one. From Fort Niagara, N. Y., the report comes: "A remarkable change has taken place in the habits of the men as to sobriety since the establishment of the canteens. Signs of intoxication are rarely seen, and the guard-house is without occupants. Nearly all of the other reports are to the same effect; and, on the other hand, the commandant at Fort Leavenworth notes an increase in the number of cases of alcoholism since the sale of beer in the canteen was stopped." The canteen has relieved our military posts of one-third of the cases of alcoholism that formerly tended to the demoralization of the individual, infraction of discipline, assaults, injuries and deaths. In conclusion it is recommended that at each post there be established a systematic course of athletic exercises to improve the physique of the men, as this does not follow from military drills.

**THE METRIC SYSTEM.**—At the quinquennial session of the Geographical International Congress held in Berne, August 10-17, there were about 280 delegates and representatives from all countries. At this Congress was passed the following resolution on August 14th: "The Geographical Congress entreats Englishmen of science to desist in future from the use of their ancient units of weight and measure in scientific and technical publications, and to employ those of the metric system only." This resolution was passed with immense enthusiasm; the applause and cheering lasted for nearly five minutes, and the vote was unanimous. The American Metrological Society has prepared a petition asking Congress to pass the following act: "That on and after July 1, 1893, the metric system of weights and measures authorized by the act of Congress approved July 28, 1866, shall be used exclusively in the customs service in the United States." Such petition the Association desires to circulate widely among those desiring to sign it, and asks each signer to mail it to his representative in Congress. It has also prepared a simple and excellent chart of the metric system which, for educational purposes, it will mail to any one asking for it for the cost price, 10 cents in stamps, to be addressed to the Secretary of the American Metrological Society, No. 41 East 49th Street, New York City. Copies of the petition can be had at the same address.

**THE GUILD OF ST. CECILIA.**—The value of music as a therapeutic process, says the *Lancet*, is about to be tested in London by practical proof. An association has been founded under the title of the Guild of St. Cecilia, which proposes to maintain a staff of skilled musicians who shall exercise their art in the neighborhood of the sick under certain regulations. The instruments to be employed, besides vocal harmony, are the pianette, harp and violin. Hospital patients are to be treated, if required, individually, by telephonic communication. The society will set itself to obtain professional opinions as to the maladies to be thus treated, and to tabulate cases in which benefit has resulted from this novel remedy.

#### BOSTON AND NEW ENGLAND.

**BOSTON CITY HOSPITAL.**—The Mayor and the members of the City Council will, by invitation of the trustees, visit the Boston City Hospital on Thursday afternoon, October 22d.

**BOSTON PUBLIC BATHS.**—During the past summer the total attendance at the public baths in Boston, which are under the supervision of the Board of Health, was 1,014,788, against 988,078 in 1890. The increase was entirely among the men and boys, the number of women and girls having fallen off. The number of the former to the latter was as 83 to 18.

**THE FIRING OF CANNON ON BOSTON COMMON.**—In commenting on our note of last week on the discharging of cannon on the Common, a daily paper remarks that something should be excused on the score of patriotism. The whole point of our note appears

to have been missed. We have no desire to limit patriotism or the use of gunpowder, but it surely is not essential that the Common should be used. There are plenty of places within a short distance of the city proper where no objection could be raised to as much noise as is necessary to insure the dignity of the State and the preservation of the Union.

**THE YALE MEDICAL SCHOOL** opened October 14th, with forty men in the entering class. The following appointments have been made: Thomas H. Russell, M.D., professor of clinical surgery and surgical anatomy, Lewis DeForrest, M.D., instructor in clinical medicine, O. T. Osborne, M.D., lecturer on materia medica and therapeutics, Graham Lusk, M.D., instructor in physiology, Charles G. Foote, M.D., demonstrator in bacteriology, Harry B. Ferris, M.D., instructor in anatomy, Joseph Townsend, M.D., assistant in the medical clinic and Robert O. Moody, lecturer on histology.

#### NEW YORK.

**CROTON WATER.**—According to a report just made by Dr. Martin, chemist to the Health Department, the Croton water, as tested by samples taken in the city, now shows a marked improvement in its condition. For the first time in a number of weeks the analysis presents a total absence of any trace of nitrites.

**THE RESULTS OF THE RECENT GALE.**—In consequence of the unusually heavy gales and high seas experienced by the incoming steamers of late, a number of the passengers have been more or less severely injured. On board the *Augusta Victoria* a curious accident happened to a mother and daughter, who were standing together when the ship gave a violent lurch. Each put out her arms to protect herself, and their elbows came together. When they were picked up it was found that the mother's left elbow-joint and the daughter's right elbow-joint were both dislocated.

**THE DEATH-RATE.**—During the week ending October 3d there was a gratifying decrease in the number of deaths reported from typhoid fever; the number being 11, while the week previous there were 24. In diarrheal diseases there was a decrease of 26 in the number of deaths, in phthisis a decrease of 30, and in pneumonia a decrease of 14. The total number of deaths reported was 737, or 74 less than the previous week. This represents an annual death-rate of 22.70 per thousand of the estimated population of the city; but the mortality was larger by 31 than the average mortality for the corresponding week during the last five years. The number of births reported during the week was 1,052.

**A CASE OF HYDROPHOBIA** is reported from Elizabeth, N. J., in a boy eight years of age, who was bitten by a large Collie dog nearly three months ago. He was so severely lacerated about the head that more than a hundred sutures were required, and he was obliged to remain for nine weeks in the hospital; from which he was only discharged September 27th.

double; the salol in the inferior stratum decomposes and renders the cause of suppuration powerless; while, in the superior, salol being like iodoform insoluble, it protects the wound from external agents, remains unaltered in the secretions of the wound while those secretions which contain micro-organisms are disinfectured.

THERAPEUTIC NOTES.

TO PREVENT COCAINE INTOXICATION. — Parker<sup>1</sup> has discovered that the unpleasant or even poisonous symptoms which occasionally follow the local application of strong solutions of cocaine in the nasal and buccal cavities may be entirely prevented by combining the drug with resorcin. This combination is also of advantage in utilizing the antiseptic, astringent and hæmostatic properties of the latter drug.

WICKERSHEIMER PRESERVATIVE FLUID. — This preparation is made as follows: <sup>2</sup>

R	Alum . . . . .	100 parts.
	Salt . . . . .	25 parts.
	Sa. p. tre . . . . .	12 parts.
	Potash . . . . .	60 parts.
	Arsenious acid . . . . .	30 parts.
	Boiling water . . . . .	3.0 0 parts. M.

After dissolving, cool and filter.

To ten parts of this solution are added four parts of glycerine and one of methyl alcohol. If preparations are to be preserved dry, they should be soaked in the fluid for from six to twelve days, according to their size, and dried without heat.

POTATO TREATMENT. — Dr. J. Solis-Cohen <sup>3</sup> reports a case in which a dental clasp, a body of very irregular shape, was swallowed. The patient was ordered to feed exclusively upon buttered mashed and roasted potatoes, and to examine his stools carefully for the foreign body. Within forty-eight hours the patient voided it, thoroughly coated with potato, to free it from which several washings were required. The author remarks that—had this very irregular body been found impacted in the œsophagus, the same treatment would have been pursued in preference to the infliction of injury upon the œsophagus in efforts at forcible extraction.

PICNI (*Fabiana imbricata*) is a plant from Chili, and was brought to the notice of the profession by M. L. Boyer, in France, in 1886, for the treatment of cystitis and urinary affections. M. de Laval <sup>4</sup> advises the use of a fluid extract made from the young twigs of the plant, and not, as used by the natives, an infusion of the woody portions, which is much less active. For cystitis the following formula is recommended (in cases of Bright's disease it is contra-indicated):

R	Ext. picni thiid . . . . .	3 i.
	Potassii muratis . . . . .	3 i.
	Syr. simplici . . . . .	3 inj. M.
	Sig. A teaspoonful every three hours.	

ANTIPIRYN IN THE INCONTINENCE OF URINE IN CHILDREN.<sup>5</sup>—Antipyrin is put forward by M. Gunde, who claims for it a place amongst the best of remedies in the therapeutics of this troublesome and common affection. He administers it in wafers containing from seven to fifteen grains, or in a mixture. This latter may have from twenty to sixty grains,

according to the age of the child, to be taken in divided doses with two hours' interval. He found that a child who took the last dose at 8 p. m. would not micturate before 5 a. m.; while if taken later, between 9 and 11 p. m., the incontinence was often entirely suppressed, even in the second half of the night. In cases where the antipyrin treatment was successful, the improvement was manifest early; but it is advisable that it be kept up for at least fifteen days. The sensibility of children to the action of antipyrin is variable. Some who are not affected by twenty or thirty grains are cured by sixty grains. Sometimes the incontinence will return, in which case the dose should be increased and the drug continued. Antipyrin is well borne by children, as a rule.

CHLORIDE OF METHYL AS A LOCAL ANÆSTHETIC. — Berezovsky <sup>6</sup> describes experiments made with a spray of this substance, and concludes that the chloride of methyl spray can be employed in all cases where an ether spray is used as a local anæsthetic; and that the former should be preferred to the latter, since it induces anæsthesia much more quickly than ether spray, it is unflammable, and hence can be safely employed in cases of cauterization, etc.; it does not undergo any change from exposure to light or air; it does not irritate mucous membranes even in children; and it is cheaper than ether, since only very small quantities are required.

# OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 10, 1891, TO OCTOBER 16, 1891.

CAPT. JOHN M. BANISTER, assistant surgeon, U. S. A., granted leave of absence for four months.

FIRST LIEUT. WILLIAM N. SUTER, assistant surgeon, U. S. A., granted leave of absence for one month, to take effect on or about October 15, 1891.

FIRST LIEUT. WILLIAM N. SUTER, assistant surgeon, U. S. A., is relieved from duty at Fort McKinney, Wyo., and ordered to Fort Grant, Ariz., for duty.

FIRST LIEUT. HARLAN E. MC VAY, assistant surgeon, U. S. A., is relieved from duty at Fort Mackinac, Mich., and ordered to Fort Wingate, New Mexico.

FIRST LIEUT. JAMES D. GLENNAN, assistant surgeon, U. S. A., is relieved from duty at Fort Riley, Kan., and ordered to Camp Oklahoma, Oklahoma Territory.

FIRST LIEUT. MERITT W. IRELAND, assistant surgeon, U. S. A., is relieved from duty at Jefferson Barracks, Mo., and ordered to Fort Riley, Kan.

CAPT. ROBERT E. BENHAM, assistant surgeon, U. S. A., is relieved from duty at Fort Hamilton, N. Y., and ordered to Mount Vernon Barracks, Ala., for duty.

CAPT. CHARLES M. GANDY, assistant surgeon, U. S. A., is relieved from duty with Army Medical Board, to take effect on its final adjournment, and ordered to Fort Yellowstone, Wyo.

CAPT. GEORGE T. BEALL, medical storekeeper, U. S. A., granted leave of absence for one month; during absence of Captain Beall, CHAS. B. EWING, assistant surgeon, U. S. A., attending surgeon, St. Louis, Mo., will take charge of the Medical Purveying Depot in that city.

# OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE HOSPITAL SERVICE, FOR THE THREE WEEKS ENDING OCTOBER 10, 1891.

VASSANT, JOHN, surgeon. Granted leave of absence for twenty-three days. October 8, 1891.

LEON, W. H., surgeon. Granted leave of absence for thirty days. October 7, 1891.

HAMILTON, J. B., surgeon. To represent the Service at the meeting of the Mississippi Valley Medical Association. October 2, 1891.

GRANWELL, J. M., surgeon. Leave of absence extended five days. September 28, 1891.

WHEELER, W. A., passed assistant surgeon. Granted leave of absence for thirty days. October 7, 1891.

FOURMAY, J. T., passed assistant surgeon. To represent the Service at the meeting of the Mississippi Valley Medical Association. October 2, 1891.

BRAYTON, W. D., passed assistant surgeon. Granted leave of absence for thirty days. October 7, 1891.

FRYER, W. J., passed assistant surgeon. To proceed to Norfolk, Va., for temporary duty. October 2, 1891.

MAYNARD, G. M., passed assistant surgeon. Granted leave of absence for twenty days. October 7, 1891.

WOLFEVER, E. M., passed assistant surgeon. Granted leave of absence for thirty days. October 6, 1891.

VAUGHAN, G. T., assistant surgeon. Granted leave of absence for thirty days. October 6, 1891.

COBB, J. O., assistant surgeon. To proceed to Buffalo, N. Y., for temporary duty. October 7, 1891.

GUTERAS, G. M., assistant surgeon. To proceed to Mobile, Ala., Pensacola and Mullet Key, Fla., on special duty. October 10, 1891.

BROWN, B. W., assistant surgeon. To report to the Medical Officer in Command, San Francisco, Cal., for duty. October 3, 1891.

# OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING OCTOBER 17, 1891.

A. F. MAGRUDER, surgeon, ordered to the "Boston."

W. S. DIXON, surgeon, detached from the "Boston," and granted leave for two months.

E. H. MARSTELLER, passed assistant surgeon, ordered to special duty, Baltimore, Md.

N. H. DRAKE, passed assistant surgeon, detached from "Albatross," and granted leave for two months.

F. W. F. WIEBER, passed assistant surgeon, detached from the "Pensacola," and ordered to the "Albatross."

GEORGE P. BRADLEY, surgeon, detached from Naval Hospital, Chelsea, Mass., and ordered to the Receiving Ship "Wabash."

F. G. BRAITHWATT, assistant surgeon, detached from "Wabash," and ordered to Naval Hospital, Chelsea, Mass.

H. G. DEYER, passed assistant surgeon, ordered to Naval Academy, Annapolis, Md.

# SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A regular meeting of the Society will be held on Monday, October 26, 1891, at the Medical Library, 19 Boylston Place, at 8 o'clock P. M.

Dr. A. T. Cabot, "Surgery and Anatomy of the Ureters"; Dr. F. S. Watson, "Stricture of the Ureters." Dr. Watson will also report a case illustrating the advantage of repeated suprapubic puncture as compared with catheterization for the relief of chronic retention of urine due to hypertrophy of the prostate.

G. G. SEARS, M.D., Secretary.

MASSACHUSETTS MEDICAL BENEVOLENT SOCIETY.—This Society will hold its annual meeting on Thursday, October 29th, at half-past eight P. M., at the house of Dr. H. W. Williams, 15 Arlington Street.

Any nominations for membership should be sent to Dr. R. Amory, Secretary, 279 Beacon St., before the day of the meeting.

# THE BULLARD FELLOWSHIPS IN THE HARVARD MEDICAL SCHOOL.

We called attention in our issue of June 4, 1891 (p. 567), to the establishment, by Mr. W. S. Bullard, of Boston, of three fellowships of \$5,000 each in the Harvard Medical School. The income derived from one or all of these fellowships may be paid to any student or member of the medical profession who shall be selected by the Faculty of the Medical School, to make such original investigations in medical science as in their opinion will be most useful to the profession and the community.

A committee of the Faculty having the matter in charge is now ready to receive applications from persons desiring to become candidates for these fellowships. Applicants should address Dr. C. P. Worcester, Secretary, Harvard Medical School, and should state the nature of the investigation which they intend to undertake, and their qualifications for carrying it on.

# APPOINTMENTS.

F. E. CREEVEY, M.D., has been appointed clinical instructor in ophthalmology in the Harvard Medical School.

J. C. CARROLL, M.D., has been appointed instructor in physiology in the Harvard Medical School.

# BOOKS AND PAMPHLETS RECEIVED.

Versuche über das Diuretin "Knoll." Von Dr. Sigmund Pfeiffer. Wien. Reprint 1891.

Evidences of the Communicability of Consumption. By G. A. Heron, M.D., F.R.C.P., Physician to the City of London Hospital. London: Longmans, Green & Co. 1890.

A Text-Book of Physiology. By M. Foster, M.A., M.D., LL.D., F.R.S., Professor of Physiology in the University of Cambridge. Fourth American, from the fifth English edition. Philadelphia: Lea Brothers & Co. 1891.

philosophical systems and to set to work in collecting facts. Permit me to quote the last paragraph of this remarkable article:

"Let us not deceive ourselves about the condition of medicine. Minds are unmistakably exhausted by the many hypothetical systems again and again cast aside only to be replaced by new ones. A few more invasions perhaps and this time of unrest will have passed by and it will be recognized that only quiet, industrious and persevering work, the true work of observation or experiment, possesses enduring value. Pathological physiology will then gradually be developed, not as the production of a few heated brains, but as the work of many patient investigators; that pathological physiology, which is the citadel of scientific medicine, of which pathological anatomy and the clinic are only out-works."

Brave words and true are these uttered by a young physician only three years after receiving his doctor's degree, words significant now, but many times more significant when they were spoken. But they were not the words of a dreamer or an idle talker. He who wrote them had already begun that "quiet, industrious and persevering work, the true work of observation and experiment," which was destined to introduce a new epoch in the history of medicine.

By a fortunate chance Robert Froriep assigned to his young assistant as a theme for independent investigation, the study of phlebitis. It would lead too far into historical detail for me to attempt to explain the position which phlebitis then occupied in pathology. Some idea may be gathered from Cruveilhier's sentence, *La phlébite domine toute la pathologie*. So firmly established at that time was Cruveilhier's doctrine that the essence of inflammation is coagulation of the blood in the veins and capillaries, that it seemed necessary to work out only certain details, such as, whether or not in suppurative phlebitis the pus is secreted by the wall of the vein. But it at once became clear to Virchow that the general doctrine rested upon no sure foundations and it was upon the foundations of the doctrine that he began to work. His preliminary studies were upon the morphology and chemistry of fibrin and the conditions for its coagulation both within and outside of the body. At the same time his attention was turned to the morphological elements of the blood, more particularly the white blood corpuscles, and here his observations on leukemia opened new points of view on the nature and origin of the white corpuscles, so that in 1846, he could say, "Herewith I vindicate for the colorless corpuscles of the blood a place in pathology." His powers of critical analysis and correct interpretation of pathological facts were at this time brilliantly exhibited in the view which he took as to the nature of leukemia, the same view essentially which is still held, in contrast to Bennett's conception of the disease as an hamiditis, a supuration of the blood. But it was in the epoch-making articles on "Plugging of the Pulmonary Artery and its Results" (1846 and 1847) and on "Acute Inflammation of the Arteries" (1847), that the best fruits of Virchow's studies of subjects suggested by phlebitis appeared. Here, for the first time, was there a clear insight into an important group of pathological facts which had been the favorite study of John Hunter and which had exercised the minds of the succeeding generation of pathologists. The doctrine of thrombosis and embolism as it was here and

subsequently elaborated by Virchow formed virtually a new chapter in pathology, well rounded as it left the hands of its founder, a monument of brilliant scientific investigation in pathological anatomy and experimental pathology. The important articles on "Pathological Pigments," and "The Pathological Physiology of the Blood" belong also to the same period and the same line of investigation. The fundamental part of these researches, together with investigations in many other directions in pathology, belong to the first Berlin period of Virchow's activity (1844-1849).

The Würzburg period, extending to 1856, was one of great and fruitful scientific work. Already in Berlin, by his investigation of degenerative cellular changes in Bright's disease and of inflammation of muscle, Virchow had reached new views as to the nutritive alterations of cells in inflammation; but it was in Würzburg especially that his doctrine of inflammation, which has exerted such a reformatory influence upon pathology, was worked out by himself and his pupils. In the article on "Parenchymatous Inflammation" (1852), and in that of the same year on "Units of Nutrition and Localizations of Disease," he has already conquered a large tract of cellular pathology. He has a firm grasp upon the nutritive and functional disturbances of cells. Further researches were necessary to reveal clearly their formative activities. In the light of the most recent views concerning inflammation, it is significant to note that in the first of these articles Virchow clearly recognizes suppuration as secondary to necrosis of tissue, and in this connection says, "Here there is certainly an inner, parenchymatous process, and if the subsequent suppuration be regarded as the outcome of inflammation, one need not hesitate to regard the degeneration of the parenchyma as an integral, neither consecutive nor accidental, part of the inflammatory process." And again at the close of the article, "not hyperemia and not exudation, nor redness, nor swelling, nor pain, do I put first, although I recognize their importance, but degeneration—I vindicate, therefore, before all for inflammation the character of degeneration."

But the brightest lustre of this period of Virchow's scientific work comes from those investigations which laid the foundations of cellular pathology. Like all of his contemporaries, Virchow at the beginning was under the dominion of Schwann's theory as to the spontaneous origin of cells from blastema. His researches upon the origin and structure of the connective-tissue group of substances, published in 1850, were reformatory for both pathological and normal histology. There followed a series of investigations which laid broad and firm the foundations of cellular pathology. Already in 1854 Virchow cast aside definitely the blastema theory of cell formation.

To describe further in detail these and the other investigations of Virchow in pathology up to the present time is impossible within the limits of an address. To do this would require a book covering nearly the whole ground of pathology. Into what corner of special pathological anatomy and of general pathology should we not be led if we attempted to follow the many hundred articles which he has written on these subjects? We cannot include here the consideration even of such a monumental work as that which he has written upon tumors.

I must content myself in the limited time remaining by directing your attention to a few salient points in-

tended especially to show the reformatory character of Virchow's work in pathology.

In his beautiful oration on Johannes Müller, Virchow says, "There is no school of Müller in the sense of dogmas, for he taught none, but only in the sense of methods." The same may be said of Virchow's school. His school means not the propaganda of certain dogmas as meant the schools of the great leaders in medicine of olden times. It is the method and not dogma which characterizes it, and the method is that of the natural and physical sciences. In 1849, in the article on "The Scientific Method and Points of View in Therapeutics," Virchow wrote: "In fact, that is true which Asclepiades of Bithynia, the father of that old school of methodistic physicians, emphasized; the method of investigation is that which is essential and determining. It is the method which distinguishes the Harveys, the Hallers, the Bells, the Magendies, and the Müllers from their smaller contemporaries. This is the soul of the natural sciences."

Observe; experiment; seek the aid of allied sciences, chemistry, physics, general biology; collect by systematic and purposeful investigation, in which the "Frage-Stellung" is correct and clear, a body of facts, and from them deduce general pathological principles and laws. It is along these lines that Virchow has worked and taught. The proper uses of hypotheses in scientific investigation he has always recognized; but important as are these uses, hypotheses are not to serve as the foundation of pathological doctrines. His early opponents, the adherents of the philosophy of nature and the so-called rationalists, accused him of leading medical science into the barren collection of facts, of letting the broad river of science waste itself in countless little streams. But both by precept and example no one has demonstrated more clearly than Virchow that the scientific mind, in the investigation of details, should not lose sight of the higher aims, the orderly classification of the facts, the search after new and loftier points of view, the establishment of general principles and laws.

This method of investigation is none other than the Baconian. Virchow did not originate it. Many before him had recognized its importance, and had applied it to medicine. Before Virchow it had already become the powerful lever of comparative anatomy, embryology and physiology. But one purpose of the historical remarks with which I began this address was to show that in pathology this method had not gained full sway when Virchow's work began, and that speculation and the construction of philosophical systems of medicine based upon speculation, were still in vogue. The application of the scientific method to pathology could not have been long delayed, but to Virchow more than to any other man belongs the credit of introducing into pathology the scientific method of investigation by the employment of which this department of knowledge has gained its rank as one of the natural sciences.

It is another great merit of Virchow to have made clear the kind of knowledge to be gained by the study of pathological anatomy. In the enthusiasm of the rapid development of pathological anatomy in the early part of this century, false and exaggerated ideas were entertained as to the relations between this subject and practical medicine and as to the kind of information to be derived from the examination of diseased organs after death. The attempt was made to construct out

of pathological anatomy alone, systems of pathological physiology. This led in France to such exclusive systems as Broussaism and in Vienna to the crasological system of Rokitansky and to the nihilistic school of therapeutics, less dangerous than Broussaism but equally unfounded. Rokitansky expressed and enforced upon his followers "the conviction," to quote his own words, "that pathological anatomy must be the foundation not only of medical knowledge but also of medical treatment, yes, that it contains everything that there is in medicine of positive knowledge and of foundations for such knowledge." Against this view Virchow pointed out that each department of medicine has its own field and must be investigated by itself and cannot be constructed entirely out of another. As he said, "Pathology cannot be constructed by physiologists, therapeutics not by pathological anatomists, medicine not by rationalists."

Pathological anatomy shows us simply the morbid changes in the organs, tissues and cells as they exist in one phase or in a series of phases. It does not show us the morbid process as it goes on in time. It does not reveal the alterations in function. Pathological anatomy is essential to pathological physiology, but the relations which these branches of knowledge bear to each other are similar to those between normal anatomy and physiology. General pathology or pathological physiology, as Virchow likes to call it, rests also upon experiment and clinical observations. It never has been and never can be successfully built up from pathological anatomy alone. Its methods are those of normal physiology. In one of his earliest publications in 1846, Virchow said: "It would be sad indeed if anatomical investigation were compelled to confine itself to the dead material, to the recognition of the completed conditions of isolated and determined products, if the entire outcome were only the description and classification of certain objects in nature. Pathological experiment remains ever the sure control for the pathological anatomical conclusion, and it will seldom be employed without disclosing to us new and valuable sources of knowledge." These words appropriately introduced the description of Virchow's admirable anatomical and experimental work on "Plugging of the Pulmonary Artery and its Results." All this needed to be said when Virchow said it, and it has not lost its force to-day.

John Hunter and Magendie were the pioneers in experimental pathology, and Virchow and Traube established pathological experiment in its inpregnable position as the most powerful aid in the development of pathological physiology.

The establishment of cellular pathology is one of the greatest events in the history of medicine. That Virchow's share in this was decisive and controlling cannot be successfully contested. The historical points pertaining to the development of the principles of cellular pathology have been often and much discussed. Virchow's investigations leading to the development of this great thought in his mind are briefly referred to in chronological sequence in the article at the beginning of the one hundredth volume of his *Archiv*. On this occasion I cannot enter into the history of the question, save to emphasize one point which is lost sight of by some of those who have written on the matter. The discoverer of a scientific fact is not he who has divined it, but he who has proved it. The opportunities for the study of the development of ani-

mal cells are furnished chiefly by embryology and by pathology. The demonstration that all cells are derived from pre-existing cells was easier to bring by the embryologist, starting with the ovum, a single cell, than by the pathologist. Hence it is not strange that embryologists, such as Reichert, Kölliker and later Remak, had discarded the blastema theory, so far as the development of the embryo is concerned, at a period when the same theory prevailed in pathology. But so long as it was not proven that in pathological formations the new cells also come from pre-existing cells, this general principle of cell development could not be considered proven. It was not until Virchow had brought this part of the evidence, more difficult to obtain than the embryological and equally important, that the truth, which he was the first to frame in the words, *omnis cellula e cellula*, was fully established. The nutritive, the functional and the formative disturbances of cells became in his hands the ground-work of cellular pathology; and although this ground-work was laid before the publication of his "Lectures on Cellular Pathology," in 1858, nevertheless these came as a revelation to most physicians throughout the world.

The principles of cellular pathology have become to such an extent an integral part of medical thought that we can hardly estimate to-day all that this discovery meant a generation ago. To do this we must put ourselves back in thought to a time when all organized pathological products, pus, tubercle, cancer and all tumors were supposed to be formed out of a primitive blastema, an exudation of some kind. Think of trying to come, under the influence of such ideas, to any coherent or intelligent opinions as to the nature and development of morbid processes.

The never-ending strife between humoralism and solidism would probably be going on to-day had it not received its death-blow from cellular pathology. The termination of this strife does not mean that we are not the heirs of great truths which came out of it, or that there is any contradiction between cellular pathology and humoral or nerve pathology in the proper sense of the terms. In 1855 Virchow said, with a cast of thought perhaps derived from his political opinions: "While we contend for the *Tiers-état* of the many little elements, it may seem as if the aristocracy and the hierarchy of blood and nerve were to be destroyed to their very roots. But it is here only usurpation which we attack, monopoly which we wish to overthrow; and once again we emphasize it that we fully recognize blood and nerve as equally authorized factors together with the other parts; yes, that we do not in the least question their predominant importance, but that we concede their influence upon other parts to be only a stimulating and moderating, not an absolute, one."

With the recognition of cellular pathology, it became clearer than ever before that the laws working in disease are not different from those in operation in health, but that they are subject to different conditions. The ontological conception of disease passed out of the horizon of scientific medicine.

Cellular pathology is not a system, a doctrine; it is a biological principle, as has been said by its founder. Its foundations have been attacked, but never have been shaken. The discoveries of karyokinesis, of wandering cells, of the migration of leucocytes from the vessels, and of the specific cellular germs of dis-

ease have only widened our views of cell pathology. Cellular pathology is one of those great principles in science which, when established, disclose new points of view, open up limitless fields for investigation, and receive the new results without a tremor in the foundations. How different this from the era of speculative systems and schools of medical doctrine, when every new discovery threatened the overthrow of the dominant system!

With Virchow's return to Berlin, in 1856, he had secured from the government the concession of a new pathological institute, to be constructed according to his own ideas and plans. In any estimate of the reformatory influence of Virchow upon pathology, his share in bringing about the general recognition of the importance of establishing pathological institutes should not be overlooked. In 1858 he wrote: "As in the seventeenth century anatomical theatres, in the eighteenth clinics, in the first half of the nineteenth physiological institutes, so now the time has come to call into existence pathological institutes, and to make them as accessible as possible for all." His ideas as to the general organization of such institutes have been the controlling ones for most of those since constructed in Germany, and for many in other countries. The importance of such institutes for the instruction of students and physicians and for the progress of pathology cannot easily be overestimated. A pathological institute, constructed and conducted like the one in Berlin, requires a very considerable outlay of money, which Virchow said must come in general from the government. In this country, however, we must look in general to private beneficence to endow hospitals and medical schools with such pathological institutes as have made Germany for many years the Mecca of those from other countries who wish to study pathological anatomy.

Virchow, like his teacher, Müller, and like one of his great predecessors in Würzburg, Döllinger, has been one of those teachers who have attracted pupils in large numbers, and have exercised a powerful influence upon their thought and development. The professorships of pathological anatomy in Germany are occupied to a very large extent by those who have been under the inspiration of his personal teachings, and many in other lands are proud to call him master.

Nearly forty years ago, Virchow wrote: "There are also those who, if they do not create the current, still give to it its direction and force. These men are not always the happiest. Many go down in the movement, or by it. Many grow weary after they have given to it their best forces. Much power and great tenacity are necessary if the individual shall not only live to see his triumph, but also to enjoy it."

He who wrote these words has lived to see and to-day enjoys his triumph. May health and happiness be his for many years to come!

SZIGETHY reports the case of a woman, aged seventy-five years, who, thirty years before, in order to support a prolapsed uterus, introduced into the vagina a ball of string previously dipped in wax. This entirely relieved her, and was worn without discomfort, so that she forgot its existence, when it was forced out of place by a violent effort. When extracted, with some difficulty, it measured seven inches in circumference, and was covered with mucus, but otherwise unchanged.

RELATIONS BETWEEN ARTERIAL DISEASE AND VISCERAL CHANGES.<sup>1</sup>

BY GEORGE L. PEABODY, M.D., OF NEW YORK.

THE subject upon which I have been designated to open a discussion this year by the committee is so very comprehensive as to necessitate some limitation of an arbitrary character. As announced upon the programme it might be held to include the results of atrophic changes in arteries, amyloid degeneration, hyaline degeneration, the various stages of atheroma, suppurating arteritis, embolism, thrombosis, and numerous other conditions besides the one of chief importance, namely, *arterio sclerosis*. It is to some few of the many important relations of the latter condition that I shall ask your attention.

Its nomenclature is still in a somewhat confused state, and about the more important circumstances of its etiological relations until recently there seemed no possibility of accord. At present, although a definite agreement has not been arrived at, there seems to be a tendency in such a direction.

An excellent and brief review of its early history is given by Orth in his "Handbuch d. spec. path." (Berlin, 1887, p. 229), where a good bibliography of the subject is also to be found.

The most generally accepted designation to-day, *arterio-sclerosis*, is the name given to it by Lobstein many years ago, and quoted by Virchow<sup>2</sup> in 1856. Rokitansky<sup>3</sup> called it simply an "auflagerungs process," and regarded the thickening in the arterial wall as caused by a deposit from the arterial blood in consequence of some dyscrasia affecting that fluid. This position he subsequently surrendered, and accepted in its stead the theory that it was an inflammatory hypertrophy, in the formation of which some exudation from the adventitia might be concerned. This change of view was partly caused by proof<sup>4</sup> which Kisse adduced, that the thickening in the vessel wall was covered by endothelium, which could not have been the case had it been due to a deposit.

The name given to it by Virchow in his classical writings upon the subject was *endarteritis deformans, s. nodosa*,—writings all of which have still the ring of science and of truth, although improved methods and microscopes have tended to modify many of the views enunciated in them. He himself enumerates many of his contributions to this subject in a short controversial article in his own *Archives* for 1879, (Vol. XXVIII, p. 380).

Virchow held that the young cells which were found in recent growths of inflammatory tissue in the vessel wall were to be traced to an inflammatory proliferation of the normal intima-cells. Traube, Köster, Talma, Cornil and Ravier, and others differed with him. Some were inclined to regard them as wandering leucocytes from the lumen of the affected artery itself, others as leucocytes from the vasa vasorum.

Köster and his pupil Trompeter not only deny the cell-proliferation of the intima maintained by Virchow,

but claim that every endarteritis is dependent on a pre-existing meso- and peri-arteritis, and that the existence of all of these forms of vessel degeneration is wholly dependent upon the presence of vasa vasorum at the site of their formation.

Heubner (1874) regarded the process as studied by him in the arteries of the brain as being due to syphilis.

Friedländer (1876) showed that this view was erroneous, that similar changes occurred in a great variety of conditions, that they were very widespread in the body and of great importance. He gave to the condition the name *arteritis obliterans*.

Baumgarten,<sup>5</sup> three years later, also showed that from the appearances of the growth in the intima alone it was impossible to say whether the disease was due to syphilis or to one of many indifferent causes. He lays great stress upon the fact that in the appearances of the adjacent tissues may often be found characteristic evidence of syphilis. It is not likely to be limited to arteries of brain, according to him, except in syphilis; but if you wish to be sure of this etiological factor in a given case, you must look carefully for other evidences of it. Thus, it may occur in close proximity to a gumma: there may be masses of granulation-tissue with caseous foci in the adjacent adventitia, and these may be in close relation to old diffused areas of fibrous peri-arteritis.

All of these conditions would assist one in ascertaining the origin of a given arterio-sclerosis: but from the structure of the growth in the intima alone, it must be borne in mind that differential diagnosis is not possible.

Practically the same is true of tuberculosis as a cause. If we find other evidences of tuberculosis, such as bacilli in the adventitia, a generalized process of tuberculosis, etc., the etiology of the case becomes simple: but from the location or appearance of the growth in the intima, no such information can be obtained. In fact, it is common enough to find in chronic phthisis near the pulmonary lesion, well-marked arterio-sclerosis which is not of tubercular origin, but is to be regarded as a part of the cicatricial process which is induced by the tuberculosis.

Somewhat earlier than this, in England, Dr. George Johnson<sup>6</sup> showed that the walls of small arteries in various parts of the body were often greatly thickened in Bright's disease, and he ascribed the thickening chiefly to hypertrophy of the muscular fibres in their walls.

In 1872 Gull and Sutton read their famous paper before the Royal Medical and Chirurgical Society, in which they took the ground that the thickening in the arterial walls in Bright's disease was due to a hyaline fibroid formation, partly in the adventitia, partly in the intima. They found similar changes in the walls of the capillaries. They found generally an atrophic condition of the muscular layer of the arteries, while the inner and outer coats were thickened. It soon developed that the hyaline appearance was an accident, due to the action of the acidulated glycerine in which they had placed their preparations.

Since the appearance of their paper in the *Med. Chir. Transactions*, 1872, numerous other writers have described a hyaline degeneration of vessels. It seems likely that several different forms of degeneration have been described under this name, a change of this de-

<sup>1</sup> Read at the meeting of the Association of American Physicians, Washington, October, 1891.

scription occurring in different parts of the arterial walls under different circumstances. It is to be considered as rather an obscure and ill-defined condition in special pathology to-day,<sup>7</sup> whose causes and consequences need further investigation.

During the past fifteen years, since the writing of Friedländer just referred to, much attention has been devoted to this subject in different countries, and many papers have been published upon it, to some of the most important of which I shall ask your attention.

Probably the most important work upon this subject that has been done since Virchow's, is that by Thoma, formerly of Heidelberg, now of Dorpat, published in Virchow's Archives, vols. xciii, xcv, civ, cv, cvi, cxi, cxii, cxiii, and elsewhere. The latest publication from him with which I am familiar is a very brief review of his work on arterio-sclerosis in the *St. Petersburger Med. Wochenschrift*, 1890, p. 360. It would be hardly feasible to present to you his arguments for the position that he maintains. His work impresses one as serious, painstaking, and ingenious, and his conclusions are of the utmost importance. We may not be able to accept them all, but in the main they seem to me to be entitled to very careful consideration. He tells us that while observers have long been agreed as to the extent to which this process is developed in the arteries, the cause of this fibrous growth in the intima has hitherto escaped detection.

It had been observed as a common occurrence in arteries whose capillary system had been previously destroyed by ulceration, or by caseous or by fibroid change. This had been so often seen that the conclusion had been reached that there must be some etiological relation between the disease in the artery and the change in its capillary system; but it was very doubtful which of the two conditions was the cause and which the effect of the other.

After carefully working over a kidney in which the process of interstitial inflammation was far advanced, one whose renal artery showed extensive new growth of the kind that we are studying, he concluded that *some change in the blood-current in an artery must result from an extensive destruction of its capillaries*; and, finally, by a very careful study of the aortic systems of nineteen bodies of fetuses and young children, he reached further conclusions which are of great interest. Even though it may seem to you, as it does to me, not quite safe as yet to accept all of the conclusions to which he thinks his work has led, still a brief consideration of them will certainly repay us; and it may be well to begin with the kidney, and to say that he concludes that the interstitial inflammation in it is the cause and not the effect, of the sclerotic process in the artery.

He finds that uniformly there develops a growth of connective tissue in the intima of the human aorta just after birth. This spreads throughout the entire arterial system which formed the direct communication between the ductus arteriosus and the umbilical arteries, at the same time that the intima of all the rest of the aortic system remains unchanged. What should cause this peculiar distribution of this growth? Is this arterial area subjected at the moment of birth to changed conditions which do not apply to the rest of the aortic system? It would seem so, and it would appear as if this newly-formed connective-tissue must be dependent upon some disturbance of the circulation

consequent upon birth, and this, he thinks, can only be a *slowing of the blood-current in the aorta* which is brought about by the closure of the two large arteries that cease to perform their function at birth, namely, the two umbilical arteries.

The physiological obliteration of these two large arteries and the loss of them as channels through which blood must be sent, causes the descending aorta to become disproportionately large, that is, too large for the due performance of its diminished function. The result must be, we are told, that the blood-current passes through it more slowly than it did in intra-uterine life. A careful review of the changed physiological conditions which occur in the aorta at birth and soon thereafter, would seem to justify this *a priori* conclusion, although it is not susceptible of demonstration. If this be so, then this part of the aorta must be diminished in size proportionately, if the circulation through it is to go on as before. The new growth of connective tissue in the intima, whose existence under these conditions is proved by the most elaborate and painstaking microscopic studies, tends to reduce the lumen of the aorta to the extent called for by the changed conditions. Not alone the existence of this new growth, which appears soon after birth, but its limitation to a definite region serves to prove that it is due to the cessation of the circulation in the placenta. The fact of its restriction to that arterial trunk which leads from the ductus arteriosus to the umbilical arteries would seem to justify the conclusion that it is due to the disturbance of the relation in point of size between the descending aorta and its branches.

In another paper<sup>8</sup> he shows that similar results follow in arteries whose capillary systems are suddenly diminished by surgical procedures, such as amputation, ligature, etc.

The so-called organization of the thrombus in arteries after ligature, had been already shown by Baumgarten<sup>10</sup> and others to be really not an organization of the thrombus. The closure of the vessel after ligature had been shown to be due in part to a proliferation of connective tissue cells from the endothelium of the intima, or from its deeper layers, in vessels whose intima is thick enough to have "deeper layers"; and in part to a mass of granulation-tissue which comes from the adventitia, having found its way into the lumen of the vessel through the rent in the media which always occurs at the site of application of the ligature. It is therefore a substitution of an organized tissue for the thrombus, rather than an organization of the thrombus which takes place, when the current of blood in an artery is suddenly checked by the application of a ligature; and the closure is partly effected by a process which is quite similar anatomically to that which we are studying.

To revert to Thoma's work. In all, Thoma has published eight papers on this subject, and numerous others on aneurism-formation and other allied topics. In the eighth paper<sup>11</sup> he gives a brief review of the most important points of his theory, and again designates this process "compensatory endarteritis," a name which he had previously given to it. He believes that the changes in the vessels come about in obedience to the following law: Every slowing of the blood-current in the arteries and veins of man which

<sup>7</sup> Fortschritte, d. Med., 1884, p. 713.

<sup>8</sup> Leipzig, 1877.

<sup>10</sup> Virchow's Archiv, 1888, 112, p. 10.

<sup>11</sup> Vide Ziegler Path. Anal. 1890, vol. II, p. 56.

is not completely and at once remedied by a proportionate contraction of the media, leads to a new growth of connective-tissue in the intima which narrows the lumen of the affected vessel and thus restores the normal swiftness of blood-current more or less completely.

The empirical explanation of the changes in the vessel-wall advanced by Thoma is this: the lesion originates in the media, which has lost its tone in some undescribed way. The defective elasticity of the media which results, allows a dilatation of the artery to take place, in consequence of which the blood-current flows more slowly than normal. This slowing of the blood-current produces a hyperemia of the vasa vasorum and a new growth of connective-tissue in the intima, with which there is associated later a similar formation in media and adventitia.

To go a little further back, the hypothesis would be that the sensitive nerve filaments in the arterial walls appreciate the change in the condition which surrounds them when the blood-current becomes slow, and in consequence they produce a reflex hyperemia of the vasa vasorum. This functional disturbance of the vasa vasorum is the direct cause of the new growth of connective tissue, first, in the intima, and then in the other two arterial coats. The tension of the arterial walls is the cause of the form taken by this growth in the intima.

As soon as the growth reaches such dimensions in any situation that normal rapidity of blood-current returns, the sensitive nerves are restored to their normal condition, the hyperemia of the vasa vasorum ceases, and no more new tissue forms in the intima, until the blood-current again undergoes changes of speed and again sets in operation the various factors in what might be called the causal nexus.

Thus, for Thoma, the explanation is purely a mechanical one; and though it has been more or less attacked, it seems to me to offer the best explanation of the cause and sequence of the phenomena that has yet been put forward. The distinction<sup>12</sup> which he draws between *primary* and *secondary* diffuse arterio-sclerosis is of importance. We have already noticed the importance which he attaches to the diminution in the resistance or resisting elasticity of the media as a factor in the etiology of the condition.

In some cases the first recognizable departure from the normal consists in the stretching of this media (whose elasticity is less than it should be) by the blood-pressure, which need not be abnormally great. This is the cause of the diffuse primary arterio-sclerosis.

This is characterized by a dilation and tortuosity of the arteries, by an eccentric hypertrophy of the media and by a diffuse, compensatory, fibrous thickening of the intima. Thus to the dilated and somewhat misshapen lumen of the vessel a size suitable to the blood-current is supplied.

From all of this there results a farther diminution of the elasticity of the walls of the affected vessels which opposes an increased resistance to the blood-current, and thus becomes the cause of a secondary hypertrophy of the left ventricle, with the development of the *pulsus celer* as a symptom.

In other cases the diffuse arterio-sclerosis seems to depend upon more remote causes, which bring about disturbances of circulation in certain localized areas. Such,<sup>13</sup> for instance, would be a destruction or narrow-

ing of smaller vessels derived from certain arterial trunks, by any pathological process.

Thus, it may be due, not merely to a weakening of the contractile power of the elements that compose the media, but to an increased resistance in the periphery. In all such cases the rapidity of the blood-current is diminished in certain arteries. This is not regulated or removed by the contraction of the media, because this tunic has lost its elasticity. Thus all the conditions are present for the development of a compensatory fibrous thickening of the intima, which will cause a diminution of the lumen and thus give to it the size and shape which the new conditions call for. To these changes the name, diffuse secondary arterio-sclerosis, has been given. This also causes the same change in the heart and quality of the pulse as the other form. The increase in blood-pressure thus caused is sometimes followed by a slight degree of hypertrophy of the media.

Both the primary and secondary forms of this affection are dependent for their origin upon a common factor, namely, a loss of mechanical contractile power or elasticity on the part of the media. Thus, the two forms of this affection are often associated in the same person and become really only two sub-divisions of a single disease, diffuse arterio-sclerosis.

Where the masses in the intima are circumscribed,<sup>14</sup> forming the arterio-sclerosis nodosa, the cause is the same as in the primary form just described, that is, a slowly developing loss of elasticity and consequent yielding of the media. This causes a slowing of the blood-current, with the consequences so often dwelt upon. The stretching of the arterial wall takes place gradually, and *pari passu* the growth of connective-tissue occurs in the intima. This being the case, the deeper layers of the *newly formed* connective-tissue must also be subjected to the stretching process as other layers are formed upon them. A consequence of this stretching is the development of degenerative changes in these outer layers of newly formed connective-tissue, those lying next to the media. Among the forms of degeneration to which this tissue is liable are calcification, fatty, hyaline and atheromatous changes. These degenerative changes seem to be characteristic of arterio-sclerosis nodosa. In some cases serious changes like these are negated by a further compensatory formation of connective-tissue in the intima over them.

The points of origin of arterial branches<sup>15</sup> seem to be favorite sites for the development of the nodose form. Thus, there develop at these sites, various circumscribed deformities of the lumina of vessels.

The hyaline and atheromatous degenerations in the new tissue are marked by a more or less distinct swelling which often causes the compensatory thickenings of the intima to project somewhat into the lumen of the vessel, and thus to interfere with the blood-current and also to narrow the lumen of arterial branches at their sites of origin in the mother vessel. Various and grave disturbances of nutrition may, of course, result in the organ to which these branches go, and it is conceivable that often a vicious circle is thus established.

Thus the diseased arteries supply less blood to a given organ than its proper nutrition requires. Local

<sup>15</sup> Virchow's Archiv. Bd. 106, III; also, Fortschritte d. Med., Bd. V, 1887, p. 59.

degenerations ensue in the organ. These changed conditions call for still less blood, and there results a further disturbance in the rapidity of the current in the nutrient artery. This causes further changes in the vessel's intima.

I have purposely omitted histological details, inasmuch as I felt sure that they would be so much more ably dealt with by my colleague.

Pekelharig,<sup>16</sup> in a recent paper, accepts Thoma's main conclusions, but he endeavors to explain the cause of the proliferation of the endothelial cells from the inner surface of the intima by supposing an alteration in blood-pressure in the interior of the diseased vessels. By some carefully devised experiments he seems to show that if the blood-pressure be diminished the intima grows. His idea is that under ordinary circumstances the pressure exerted on the intima by the blood is sufficient to prevent any growth except such as may be needed for repair, but, that if the pressure be diminished, then the endothelium can grow in excess of the needs of the system until a normal pressure be again exerted upon it.

How are we to account for the alteration in the rapidity of the blood-current, if that be the initial local factor in the series of events which leads to the development of the arterial changes under consideration? To this question the answer is vague and unsatisfactory. The change in rapidity of current is not susceptible of proof. We are to infer its existence from the facts which have been already adduced.

When we endeavor to explain its cause we begin to deal in generalities which are unsatisfactory to the seeker after the exact.

Its cause<sup>17</sup> is to be regarded as a general disturbance of nutrition, which may be due to infectious of various kinds, or to different kinds of pathological processes or to senile changes. These general disturbances of nutrition cause disease not only of the arteries, but of the veins and capillaries as well.

Arterio-sclerosis can occur in a great variety of conditions. Unless we accept Thoma's conclusions, it is still often difficult to determine whether it is the cause or the effect of the morbid process by which it is accompanied. It is a common occurrence in inflammations in which the formation of connective tissue is at all a prominent factor. Thus it is often seen in connection with cirrhotic changes in the kidney, in the testicle, in chronic inflammatory processes of lungs, of Fallopian tubes, in many neoplasms, especially those accompanied by abundant connective-tissue formation, such as elephantiasis, fibroma, carcinoma, epithelioma. Heredity, syphilis, gout, rheumatism, old age, chronic alcoholism, all seem to be important etiological factors in the development of this arterial change, and, to these, Thoma has added functional arterial strain.

Sack<sup>18</sup> has studied the topographical distribution of the disease throughout the arterial system.

He finds that physiologically there exists in the common carotid a sub-endothelial layer of connective-tissue which increases steadily in thickness, and never becomes very thick. If diffuse arterio-sclerosis be present, this growth in the carotid increases very materially in thickness.

The explanation of this condition of things in the carotid is this: This artery has attained almost its com-

plete development by the tenth or twelfth year; as the rest of the arterial system grows after that and accommodates more blood, the carotid is subjected to frequent or even constant stretching. After a time this overstretching causes it to lose much of its elasticity; it becomes unable to return to its proper size, and becomes too large for the amount of blood that it has to transmit. Under these circumstances it is easy to account for a compensatory sclerosis. Sack's results in the matter of topographical distribution of this disease show a difference between the diffuse and the nodose form. The former selects the arteries of the extremities, the latter, the aorta and carotid.

The arteries of the extremities are subjected to more hydrostatic pressure than those of the interior of the body, by reason of their remoteness from the heart, and hence they are more likely to be diffusely dilated, and to need the compensatory sclerosis in consequence.

The nodose form depends, however, upon local weakness or disease of the media; and it is in the aorta and carotid that the force of the heart's action is likely to cause such localized stretching, especially by reason of the branching and change of direction to be found in them.

Sack gives a scale showing frequency of occurrence of sclerosis of all forms and grades in different arteries, with 100 as a maximum. The following is the order of frequency: tibialis anticus, 94, ulnar, 92, radial, 79, popliteal, 54, ascending aorta, 58, common carotid, 58, external iliac, 53, abdominal aorta, 52, brachial, 51. When it occurs as a degeneration of old age, it has a great variety of locations. Its development may be very slow, and it may chiefly affect the aorta; it may be confined to the arteries of a single organ or it may extend to those of several organs, or it may be found in many or in most of the organs.

If none of the recognized causes exist and still the lesion occurs, then we are inclined to ascribe it to tobacco or lead, or to some of the exigencies of life (not more nearly defined) to which the patient has been exposed. Of late, too, endocarditis, typhoid fever and scarlet fever have been included among the remote causes of the lesion.

It it occur in the vasa vasorum, it may be the cause of a localized atheroma, this degenerative process following upon the interference with the blood-supply to vessel's wall.

Let us consider, now, some of the more important effects of these changes in the arteries. Of late years, much has been written upon the subject of the relation of arterio-sclerosis to aneurism;<sup>19</sup> and although all agree that the two conditions often occur together there seems to be no little discrepancy with regard to their relations from an etiological point of view.

It may be interesting to devote a few moments to this matter, with the premise that it is not claimed by any one that arterio-sclerosis is the sole cause of aneurism.

It is susceptible of experimental proof<sup>20</sup> that in the early stages of the affection the arterial walls are weakened and dilatable. The walls are still elastic, but less elastic than normal, so that if the pressure within be gradually increased the lumen is increased to a much greater extent than is the case with a normal artery.

under similar circumstances. In the next stage the thick layer of connective tissue in the intima renders the vessel fully able to withstand momentary increments of pressure from within.

It seems probable, therefore, that the arterio-sclerotic aneurism develops during the first stage of arterio-sclerosis. Thoma tells us that at this time the wall of the artery is so far weakened that it is perfectly easy to produce artificial aneurisms in the vessel removed from the body during life or after death by a pressure of from twelve to twenty-four centimetres of mercury. This cannot be done either with normal arteries or with such as present an advanced degree of arterio-sclerosis.

It is of interest to know that the early stage of this lesion, the time when the arteries are easily dilatable, is supposed to last only a year. As a result of experiment and calculation, the inference has been drawn that a year after the beginning of the disease in a vessel, the intima is to such an extent re-enforced by newly formed connective-tissue that liability to formation of aneurism may be excluded.

It should be remarked that this period of time applies, not to the whole arterial system (in Thoma's calculations), but to each diseased vessel. That is to say, the various arteries may become diseased in succession throughout the body; and from the beginning of the development of weakness in the muscular coat in the case of each vessel, a year must be allowed to elapse before liability to aneurism in that particular artery has passed.

"Every individual who is the subject of arterio-sclerosis is thus for a year exposed to the danger of aneurism in all parts of his arterial system. This period occurs chiefly between the ages of thirty-five and forty-five years." We should probably want stronger evidence of the truth of such exact inferences than seems to be forthcoming before we accepted them.

It is of great clinical interest that this weakness of the arterial wall which marks the early stages of arterio-sclerosis can be diagnosed by ophthalmoscopic examination. The evidences of its presence are said to be tortuosity of the arteries, pulsation and locomotion visible in them (without other explanation, such as chlorosis, anaemia, neurasthenia), opacities in their walls, often a diminished lumen, hyaline degeneration of some vessels of papilla, occasionally aneurism of the central artery, and oftener varicose veins. Complete obliteration of an artery has been seen, and thickening of the walls of veins with partial obliteration of their lumina.

It is altogether likely that changes like these in the central artery of the retina, and in the ophthalmic artery, are associated with changes in the internal carotid. It is believed that the rest of the arterial system may be intact and yet serious changes show themselves in the carotid and its branches.

(To be continued.)

QUARANTINE IN THE SUEZ CANAL.—An international conference is to assemble shortly at Venice, in order to deliberate, at the instigation of Austria-Hungary, on the subject of the passage of the Suez Canal by vessels in so-called "quarantine."

## LEAD PARALYSIS.

BY S. G. WEBBER, M.D., BOSTON,  
Superintendent of the Adams Nervine Asylum.

IN 1882,<sup>1</sup> I published several cases of lead-poisoning in which the paralysis was limited to or most marked in the legs, the symptoms being due probably to a peripheral neuritis. During the last few years several other similar cases have come under my notice. In that article I reviewed at length the results of autopsies and the views of observers in regard to the seat of the lesion in such cases, as published up to that time.

The view that the muscles are chiefly affected has found but little support, Friedländer being the principal advocate of this localization.

Erb, E. Remak, Eulenberg, Monakow, Bernhardt, de Watteville, Birdsall, favor the view that the spinal cord or brain are the parts primarily affected. Westphal, Leyden, Zunker, Gombault, Charcot favor the view that the lesion is primarily a neuritis. Not all these authors have been able to examine the nerves and nerve-centres in cases of lead paralysis.

Since the publication of the previous paper on this subject there have been several autopsies published.

Wynter<sup>2</sup> found lead in the brain, in case of lead-poisoning.

Oppenheim<sup>3</sup> found the ganglion cells of the spinal cord diseased. While the white substance was normal the gray substance of the anterior columns (only in a doubtful degree of the posterior column) was diseased throughout nearly the entire cord. The chief centre of the diseased changes was the cervical and lumbar enlargements, while above and below these the intensity of the changes diminished. He draws the inference that these cells must have been disturbed in their function long before they showed any material changes which could be recognized.

Schultze<sup>4</sup> found the cord normal. He found, on the other hand, an atrophy and destruction of most of the nerve fibres in the trunk of the radial, below where the branch for the supinator longus is given off. Above, the change was less, so that just below the plexus there were no clearly abnormal fibres.

Schultze thinks that the pathological changes are to be found in the nerves primarily, that in generalized lead paralysis a central lesion in the anterior cornua may be added to this.

Osw. Viorid<sup>5</sup> found in one case no change in the spinal cord nor nerve roots; especially was there no change in the cervical portion of the cord.

"An undoubted pathological change is nowhere found in the spinal cord and its roots."

There was extensive degeneration of the right radial and median nerves, less marked of the ulnar nerve.

He considers that there is no analogy between the pathological changes found in lead paralysis and those found in infantile paralysis.

Alexander Westphal<sup>6</sup> reports thirteen cases of saturnine encephalopathy with two autopsies. His conclusions are:

(1) That there is a direct influence of lead upon the brain. This toxic influence is manifested by general cerebral symptoms, as well as by focal symptoms. Especially are to be counted among these that peculiar neurosis, which is accompanied with hemianæsthesia

<sup>6</sup> *Ibid.*, xix, 1888, p. 620.

and psychic disturbances. At the same time single cerebral nerves (especially the optic) may be subject to anatomical changes from the poison.

(2) There is an influence of lead upon the cerebral vessels, and thereby is produced arteritis and its consequences (hæmorrhage, encephalomalacia).

(3) Influences of lead upon the kidneys with uræmic cerebral symptoms.

(4) Finally these causes may be combined together.

It would seem from the results found in the majority of autopsies that neuritis is the most common lesion in these cases, but it is not the only change due to lead. Yet it is not in accordance with what we know of neuritis to have in it exaggerated deep reflexes and ankle clonus. The cases in which the symptoms of lateral sclerosis were prominent could not have been cases of neuritis. Thus:

Cases I and III were clinically typical cases of sclerosis of the lateral columns except the anæsthesia in Case I.

Case II had some of the symptoms of lateral sclerosis, but was less simple, and with these there were cerebral symptoms.

Case IV had the exaggerated deep reflexes, but otherwise did not resemble lateral sclerosis.

Cases V and VII were typical neuritis.

Case VI had some spasmodic action of the legs, which is less commonly seen in neuritis, and the cerebral symptoms are rare in neuritis. Otherwise the symptoms pointed to the nerves as the seat of the lesion.

Clinically, then, the symptoms, in some of these cases, would indicate that the lesion was in the nerves; in other cases, that the lateral columns of the cord were chiefly affected. In others it would seem as though the nerves or cord and the brain were both affected together. These might be considered mixed cases.

As might be expected, judging from the differences of opinion as formed from the results of post-mortem examinations, the analysis of the clinical features of these few cases would lead to the conclusion that no one nervous tissue is exclusively affected, but that all may be subject to changes due to the poison of lead.

*Case I. Anæsthesia, partial analgesia of legs, exaggerated reflexes, loss of motion, contracting of legs, lead in urine, cerebral symptoms, — recovery, relapse.*

Miss A. G., age nineteen, student, was admitted to the Adams Nervine Asylum, October, 1885; for nearly a year she had had a tired feeling, after that a numbness in her limbs and a feeling of weakness, no headache nor pain. She was obliged to leave school in April on account of this general loss of strength and feebleness in her legs. There were no other symptoms at that time.

There was found marked anæsthesia on both sides as high as the umbilicus; partial analgesia to the same height; muscular sense or the sense of position much diminished, especially on the right. Plantar reflex more marked on left; patellar tendon reflex strong on both sides; ankle clonus strongly marked on both sides; a light patellar clonus on the left, not on the right.

The legs were stiff; it was not easy to move them passively. During the night the knees were drawn up, and in the morning the patient had considerable difficulty in straightening the limbs on account of the stiffness, worse on the right. The knees and ankles had been swollen; the hands and fingers had not been. There was a slight uncertainty in the motion of the

hands with the eyes shut. The patient was unable to stand; she could sit in a chair if well supported; she could not move her toes, but could slowly extend the legs or draw them up.

There had been no colic, no lead line on the gums. Except the above mentioned slight inco-ordination of the hands, there were no symptoms above the waist. After she had taken iodide of potassium for a week, lead was found in the urine.

She gained somewhat before leaving, had more sensation in her limbs; after about two months could tell whether her feet were hot or cold, and sensation was more natural half-way up to the knees. In March she wrote that she could sometimes move her toes, but the legs moved when they got ready, not when she wished to have them.

Later she was taken to a "Christian Scientist," and was much injured by excitement. She became so bad that there was a question, whether she had not lost her reason; but she subsequently went West, where she had more judicious treatment, slowly recovered the use of her limbs, and could walk well without difficulty. Four or five years later she again was partially disabled; whether she was again exposed to lead I have not learned.

When first seen she was not especially nervous, but the hysterical condition was developed during the excitement caused by visiting the "Christian Scientist," showing that the nervous system was in a condition to be easily upset.

*Case II. Cerebral symptoms, anæsthesia, severe pain, exaggerated reflexes, loss of motion, lead in urine, — great improvement.*

Mrs. II. entered the asylum early in 1888, age twenty-five. She had been sick at times for three years since a miscarriage. She gradually lost strength, and was finally obliged to give up her housework. She felt tired out, the left side ached and was numb and cold, sometimes with a sinking feeling. The right leg gave some trouble, but less than the left. For about three weeks she had been dizzy; she had twice fallen at least partially unconscious; then her head felt badly; she was numb and unable to move for a while. She said she had a nervous attack the previous summer, in which it took several persons to hold her. She had a poor appetite, but nutrition seemed to be fairly good; the least exertion, however, tired her and exhausted her strength.

The pupils were rather large and reacted well; co-ordination of hands was good and sensation normal in hands; she lay with her feet crossed and extended; the great toes were strongly flexed; sensation to a light touch and to pressure was absent below the knees on the left, diminished on the right, diminished on the thighs in some areas.

On striking the ligamentum patellæ on the right to test for reflex, a continuous tremor of the leg and foot was excited. Ankle clonus of short duration was present on both sides. Pressing the left foot up to excite this caused severe pain in the left knee, followed by spasm and rigidity of the legs, especially of the left. The back was sore and tender to the touch. She could not walk; was confined to the bed; she slept poorly; the catamenial flow was profuse, attended with much pain and nausea. Her manner of talking and acting was decidedly hysterical; but she seemed really to suffer much in her back and the ovarian region. Lead was found in the urine.

The galvanic current was used to the spine, the legs and over the ovaries with relief to the pain. After several days she slept better, and finally she slept all night when the electricity was used. She ate more, and sat up.

May 1, it is recorded: "No ankle clonus; patella tendon reflex apparent, but obscured by muscular rigidity: sensation about both knees acute and painful."

She gained, and the last of October could walk about her room without assistance except such as she got from leaning on the furniture. All the muscles reacted naturally to the electric current. After leaving the asylum she relapsed, and did not do as well as I hoped she would.

*Case III. Loss of motion, contraction in legs, exaggerated reflexes, lead in urine, — no gain.*

Mrs. B., age forty-four, admitted June, 1888, was quite well till four years previously, then she first noticed numbness in the right leg, and that leg felt heavy; the gait was unsteady. Three years before entrance she had a child, and was somewhat better afterwards, so that she could walk about and do some housework. For about three months her legs felt strong, then they began to drag as before. She fell, striking her back, without loss of consciousness; since then has had pain in the small of the back and between the shoulders; otherwise she has had no abnormal sensations.

There was a swelling of the feet. After staying in bed a few days this improved, but she could not walk. The bowels were constipated. The legs drew up, flexing at the knees, and then in a short time extended again. On waking in the morning she found the legs flexed at the knees, especially if she was constipated. Sometimes the legs got crossed. Appetite and digestion were fair, and she got a fair amount of broken sleep. The skin was dry; there was oedema of the legs below the knees; sensation was about normal in the legs. The motion was much impaired in the legs; she could not rise without assistance. On moving the legs passively, they were found to be stiff; patellar tendon reflex was exaggerated; there was marked ankle clonus; plantar reflex was stronger on the right; the abdomen was full and tympanitic; the hands and arms were all right. A large amount of lead was found in the urine after she had taken iodide of potassium.

She made no material gain, and the last that was heard from her she could not walk, and was in essentially the same condition as when she left the asylum.

There was less nervousness and instability than in the two preceding cases.

*Case IV. Loss of motion, anæsthesia in legs, exaggerated reflexes, lead in urine, herpes zoster, cerebral symptoms, — improvement, relapse, recovery.*

Mrs. C., age sixteen, was seen in October, 1881; aching since March; gave up school then. Going to school she walked rather over a mile, going that distance four times a day. She walked it easily in twenty-five minutes. Two years before she rode much of the time. At Christmas she was tired, but it seemed to be only natural fatigue. There seems to have been no serious trouble before March. She stayed at home from school three days on account of being tired and feeling poorly; was on the bed most of the time, slept much, was not feverish, had no sore-throat, had a dull headache. She then went to school

for half a day, and on coming home could not walk, was very nervous, burst into tears; said that she could not get home, her limbs were numb and weighty. After that she lay down most of the time, slept much during the day all summer, could not walk much, was easily tired, going up stairs made her limbs ache and caused short breath. She cried much and easily.

During the summer she was at the seashore, and after her return her back ached when she rode. When tired her legs felt heavy, and sometimes ached as high as the knees, also she had a sleepy feeling in them. She had a dull headache most of the time.

When first sick there was twitching of the legs in sleep, but this had ceased when first seen. Patellar tendon reflex was strong; a slight ankle clonus was present.

Lead was found in the urine after she had taken iodide of potassium; lead was also found in the drinking-water.

About June she had a very painful attack of herpes zoster. She gained much after this, and was in a fair way to get about. The family moved into another house, and soon after she was less well. The symptoms took a more hysterical character: she was nervous, tremulous, easily moved to tears, and her general nervous condition was much worse. She was more easily tired and upset by company or by little vexations. It was found that the drinking-water was again liable to be contaminated by lead; this was corrected, and there was a slow but constant improvement until she fully regained her health.

*Case V. Cerebral symptoms, loss of motion in arms and legs, pain, reflexes absent, lead in urine — great improvement.*

Mrs. L., age forty-five, had been ill six or seven months, at first having strange, disagreeable feelings and general malaise, with dyspepsia. She had severe nausea and was fed by the rectum, was delirious, and mind was impaired afterwards for four or five weeks. She had had considerable discomfort in legs and hands, and was unable to grasp objects well. At times she had pain in her joints, her legs were weak, and she could not stand without support. The left leg could not be fully extended, the right could be. There was diminished muscular sense in the left leg; a light pressure on the calves caused pain. Rubbing hands and toes caused a feeling like electrical shocks. A light touch was not painful. There was diminished sensation on both sides.

The pupils reacted and the eyes moved naturally; tongue was protruded straight; motions of the face were good. There was a slight loss of coordination in the hands; no tremor of hands. Sensation of hands, feet and legs was natural. Patellar tendon reflex was absent on both sides; there was no ankle clonus. The left leg was somewhat contracted at the knee, and extension caused pain at the hip. To the faradic current the vastus internus on both sides almost failed to respond. Action of the peronei and the interossei of the fingers reacted very poorly. The flexors in the forearms did not react readily; the other muscles of arms and legs responded very well. An unusually large amount of lead was found in the urine.

There was a peculiar childishness in the patient's mental condition; it seemed as though the brain's action was enfeebled as the muscular power had been. She could not read, could listen to reading only for a

short time. There was, however, a firm determination to get well, and an unusual perseverance in the use of exercises to strengthen the muscles. She steadily gained, and finally was able to walk with only a cane for support, and could use her hands fairly well.

*Case VI. Spasmodic action and loss of power in legs, deep reflexes absent, cerebral symptoms, lead in urine, — improvement.*

Mr. B., age fifty-one, called to see me in 1890. He had been ailing for a year or more. He had exercised much in rowing and in other sports. He first began to grow weak in his legs and lost control of his rectum. He felt as if he had an iron on his back tied around tight. There had been hæmorrhoids seven years before and at that time he had a mucus discharge from the rectum. He grew weaker in his legs, there was numbness of rectum and back, a girdle sensation about the abdomen. His legs had a sleepy, prickly feeling. Once in a while there was pain in the back during the previous two months, sometimes pain in the legs, no lancinating pain. Once, while riding, he had a peculiar sensation in his rectum, and had to get out and walk. With his eyes shut he walked poorly. Patellar tendon reflex was absent.

He lived for four years where the drinking-water came through a quarter of a mile of lead pipe from a spring. After taking iodide of potassium, lead was found in his urine.

I did not see him again until February, 1891. He had had hæmorrhoids and these had been operated upon in the interval. He was no better, rather worse. There was the same girdle sensation about the body at the level of the ensiform cartilage extending nearly the width of the abdomen.

The legs twitch when he goes up stairs, so that it is sometimes easier to take two steps at a time. When sitting the legs are strongly adducted. He sometimes staggers in walking, legs twitch when he lies down. There is little or no pain. Numbness about rectum and genitals. Patellar tendon reflex gone. There was no inco-ordination of hands, no disturbance of eyes, tongue was protruded straight.

There was a very marked hypochondriacal or hysterical element noticeable in the patient. He was extremely anxious about himself and inclined to dwell upon his disability. When he went out to his business he was better than when he staid at home. He would declare in the morning that he was worse, could not walk, could not go down town. With a little encouragement he would start off walking with difficulty with the aid of a cane, after getting a short distance from the house the cane would be put under his arm, and he would walk without it; or he would meet a friend and stand talking with him, forgetting all about his infirmity.

When I gave him a prescription for iodide of potassium, five grains to a dose, I cautioned him that it might be too much; he had unpleasant sensations from it but not such as are caused by the iodide. On reducing the dose he went on quite well. One Saturday he did not go in town to business. Sunday morning, after a very good night's rest, he had a very nervous spell, said he was in terrible agony, but after a little while he did not mention this again but said his family did not understand that he was continually losing the use of his limbs; he tottered and made terrible work in walking. In a short time a friend came whom he was pleased to see. Nothing more was

heard about the walking and on Monday morning he went to town as usual.

When last seen he was better, having less of the girdle sensation, less bad feeling in his fingers and less numbness in the rectum and genitals, and was looking better in the face.

*Case VII. Numbness, loss of power in legs, lead in urine, cerebral symptoms, — rapid recovery.*

Mr. M. had been ailing two months previous to my seeing him. He had a pricking feeling in his fingertips and toes. He had had syphilis for which he had been treated for two years. He had had no skin affection, but four months after the first lesion he had a sore throat. He had formerly used spirits and tobacco.

About a month before he came under my notice he had had a fissure of the rectum for which he had used a large amount of lead as an injection. He had used canned food, his drinking-water had come from many sources; so it could not be learned how much lead he may have obtained from that.

Two months before the visit the numbness began, then his legs got heavy and he could hardly walk, then he was in bed two weeks with pneumonia. It was necessary for him to travel after this attack of pneumonia and the nervous symptoms were aggravated; the numbness was worse, the heaviness of the legs became worse, his knees and ankles became weak and it was difficult for him to walk. There was no numbness above the middle of the legs nor above the wrists, the arms were weak as well as the legs. There was no pain except twice in the middle of the forearms. He dragged both legs, the left the more. The pupils reacted to light, the left was slightly the larger; the tongue and the facial muscles acted naturally, there was a slight inco-ordination in the left hand, less in the right; patellar tendon reflex was absent. Sensation was blunted in the legs, higher it seemed normal, it was perceptibly delayed in the tips of the fingers, slightly delayed in the palm and much so on the palmar surface of the fingers, both hands alike.

After taking iodide of potassium, lead was found in his urine. He was given the iodide and made an unusually rapid recovery.

He was very nervous, almost hysterical, and anxious about himself, and probably appeared worse than he really was.

In April I saw him again: he said he was perfectly well and seemed so to be. The patellar tendon reflex was normal, he walked naturally, sensation was normal.

Syphilis might be suspected, but the dose of iodide was not more than seven grains, and it would be quite as unusual to have syphilitic neuritis recover so speedily with so small a dose as to have lead neuritis recover so in so short a time. Though he seemed very badly off when first seen, much of the unfavorable appearance was probably due to his extreme nervousness.

Dr. Minot reports a case of lead paralysis with rapid recovery.<sup>7</sup>

The prognosis in these cases of lead paralysis even when they seem very severe, is generally favorable to judge by these and similar cases. By a persistent use of iodide of potassium, with massage and electricity, even seemingly hopeless cases have improved or recovered. In a few cases, especially if not seen early enough, the termination is unfavorable. Serious cerebral symptoms are probably more unfavorable than the spinal and peripheral symptoms.

# THE QUESTION OF A MIXED INFECTION FROM SYPHILIS AND TUBERCULOSIS.

BY JOHN T. BOWEN, M.D., BOSTON.

[THE following formed part of a paper read before the American Dermatological Association at Richfield Springs, N. Y., in September, 1890. It was not published at the time, partly because some further investigations in the same line were contemplated, and partly because the coming of tuberculin promised an easy and definite solution of the question at issue. Tuberculin, however, has proved disappointing, not only from a therapeutic, but also from a diagnostic standpoint, for although it has been shown to have a relative diagnostic value, it cannot be relied upon as an absolute test. It has been thought proper, therefore, to put upon record the experimental studies embodied in this paper, which, although few in number, may serve a purpose in connection with others of a similar nature. Since the paper was written a short *résumé* of a dissertation on this subject by Leppenheim, Würzburg, has come to my notice. The material was offered by a case of lichen syphiliticus, in which signs of tuberculous infection also were present. No tubercle bacilli were found in the tissue excised. A papule of the lichenoid eruption was inserted in the eye of a rabbit, but failed to produce tuberculosis.]

The histological characters of tubercle were, as is well known, considered for some time to be pathognomonic of this affection. The Langhans giant cell with its peripherally arranged nuclei, necrotic centre and protruding processes, was considered when taken in connection with the other characteristics of the so-called Wagner-Schuppel tubercle to make up a picture found only in true tuberculosis. Later, doubt was thrown on this view by the discovery of typical Langhans cells in other conditions.

Baumgarten, who has interested himself especially in this subject, published a series of papers, showing that he had found Langhans cells in gummatous nodules of the liver, in gummatous lesions of the dura, and in the tissue about vessel ligatures. Of six cases of gummatous orchitis, three were found to contain Langhans cells in large numbers. Hence, he concludes that Langhans giant cells can no longer be considered typical of tuberculosis. In 1884, however, in a paper published in Virchow's *Archiv*, Bd. 97, Baumgarten declares that he has modified his previous view somewhat, and that he regards those cases of syphilis where Langhans cells and the Wagner-Schuppel tubercle structure are present, as mixed forms of syphilis and tuberculosis. For the support of this view he adduces the following reasons:

(1) It appears improbable, from his own observations and those of others, that any other process besides tuberculosis is that is developed spontaneously in the human body, possesses the power of producing Langhans giant cells or the structure of the Wagner-Schuppel tubercle.

(2) The subjects who present gummata in which the Langhans cells and the type of the Wagner-Schuppel tubercle are found, almost always shows unmistakable signs of a present or past tubercular infection.

(3) The gummata of syphilitic subjects who can be positively demonstrated to be free from tubercular contamination, are never found to contain Langhans cells or the tubercle structure.

(4) The initial lesion of syphilis, as it is caused by the direct action of the syphilitic virus, and must be looked upon as the type of the specific affection of the tissues, never contains Langhans cells or a typical tubercular structure, but accords histologically with the pure gummata of skin, periosteum and internal organs.

In 1889, the subject was taken up anew by Michelson, who published an interesting article in Virchow's *Archiv*, entitled, "Is lichen syphiliticus the product of a mixed infection of syphilis and tuberculosis?" He publishes a sequence of three cases of small papular, lichenoid eruption in members of the same family, which proved to be examples of syphilitic lichen. Papules excised from two of these cases showed in the corium a typical Wagner-Schuppel tubercle structure, with Langhans giant cells. This accords with the anatomical researches of Grifflini, who in 1875 described the papule of lichen syphiliticus as made up of nodules of tubercular structure immediately below the papillary layer, containing giant cells more or less branched and with peripheral nuclei, surrounded by a mass of epithelioid and lymphoid cells.

Neumann also has described and pictured giant cells in these papules of lichen syphiliticus that accord pretty well with the Langhans type.

Michelson, therefore, considers that there are grounds for questioning whether the syphilitic lichen be not a complication of syphilis and tuberculosis, as Baumgarten had suggested for those gummatous lesions where Langhans cells are found. This view he finds supported by the fact that the lichenoid syphilide is found in cachectic or tubercular subjects, and that it is especially obstinate and often relapses. His attempts to find tubercle bacilli in the excised papules, were, however, totally unsuccessful.

My attention having been called to the structure of the lichenoid syphilide by this article of Michelson's, an opportunity to study it was offered by what was to all clinical appearances, a typical instance of this form of specific eruption, which I will briefly describe.

CASE A. T. D., male, nineteen, May, 1890.

Of good family history, had been well, with the exception of an abscess in the axilla a year and a half ago. Date of infection uncertain. Six weeks ago the eruption appeared on the back of the neck extending downward. Now presents a grouped, lichenoid eruption of trunk, arms and legs with a few large papules interspersed. The glands behind the ear are enlarged, and a long chain of epitrochlear glands can be felt. Glands in groin not especially altered. No alopecia. Nothing abnormal found on physical examination of the chest.

The patient was treated with mercury by inunction and appeared ten days later with an iritis, whereas the cutaneous lesions had diminished.

July 8th. Eruption had practically disappeared, leaving only a few spots of pigment. Iritis much improved.

No possible doubt can be entertained, from the clinical appearances, and from the result of treatment, that this was a typical instance of lichen syphiliticus. No symptoms of tuberculosis could be found. The patient's appearance was, as is so customary in this form of syphilis, somewhat cachectic, but his general health improved rapidly as the eruption disappeared.

*Histological Examination.*—Several papules were removed from the back. The horny layer somewhat

thickened. In the centre of each papule examined, could be seen the follicular opening, enlarged and filled more or less completely with horny matter. The papule is seen to be caused by an infiltration of cells around the follicle in the upper part of the corium. The papillæ over this cell infiltration are effaced. The infiltration is made up of epithelioid and round cells with very numerous Langhans giant cells. There was no cheesy degeneration or suppurative change.

Sections from two different papules were examined for the tubercle bacillus by Ehrlich's method with much care. Forty-four sections from one papule and twenty-nine from another were searched with an absolutely negative result.

*Inoculation Experiment.*—May 21, 1890, two more papules were removed antiseptically and after being crushed and mixed with sterilized water, were injected into the abdominal cavities of two rabbits.

July 9th. The two rabbits, who had remained apparently healthy, were killed. Examination showed nothing abnormal, with the exception of some foci with a necrotic centre in the liver of one of the rabbits. The amount of fibrous growth at the periphery suggested a not very recent process, and there was nothing in their histological appearances to warrant the diagnosis of a tubercular process, nor could the bacillus of tuberculosis be detected.

This case, while it accords with the descriptions of Grifflin, Neumann and Michelson as to the histological structure of the lichenoid syphilide—showing it to be made up of a cell structure that cannot be differentiated from that of tubercle—brings no support to the theory that this form is a combination of syphilis and tuberculosis. There were no tubercular symptoms, no bacilli were found, and inoculation experiments failed in two instances to produce tuberculosis.

Another instance of the presence of Langhans giant cells in a presumably syphilitic tissue was found in the following case:

CASE B. E. H., male, age thirty-five, May, 1890. No history of previous troubles. For three years has had an affection of the scrotum which has repeatedly broken down into ulcerations. Was operated on in March, 1888, when he says a part of the right testicle was removed, and that the wound never healed entirely. He now presents an ulceration of nearly the whole scrotum, without apparent implication of the testicles, with somewhat indurated edges. In places are islets of firm, cicatricial tissue.

Patient was treated with iodide of potash in tea-grain doses three times a day, and the ulcers dressed with boracic acid ointment. In a week a great improvement had taken place, and at the end of three weeks the ulceration had entirely healed.

*Histological Examination.*—Pieces of tissue excised showed beneath the ulcerated surface, in the lower layers of the corium, a granulation tissue, and in almost every section one or more typical Langhans giant cells. No arrangement of the cell growth in clusters, such as is seen in the typical Wagner-Schüppel tubercle, was found in this case. Examination by Ehrlich's method of a small number of sections failed to detect a single tubercle bacillus.

*Inoculation Experiment.*—May 21, 1890, secretion and pieces of tissue were taken from the ulcer of the scrotum, were mixed with sterilized water, and injected into the peritoneal cavity of two rabbits. July 9th, the rabbits, who had appeared healthy, were killed,

and post-mortem examination revealed nothing abnormal.

The diagnosis of syphilis, which could not be positively made from the clinical appearances, was rendered pretty clear by the result of treatment with the iodide of potash. The histological examination on the other hand was able to throw little light, as appearances were found that have been by some considered characteristic of tuberculosis. The failure to find the tubercle bacillus, and the result of the inoculation experiments, while they offer no conclusive proof that the affection was not of a tuberculous nature, may be accepted as negative evidence of considerable weight. There can be little doubt that the ulcer was a syphilitic gumma, and the presence of the Langhans cells accord with the reports of those who have observed these cells before in lesions of this nature. The negative result of the bacteriological search and of the inoculation experiments, brings no support to the view that there was a complication of syphilis and tuberculosis.

It may, then, be positively asserted, that, in certain syphilitic lesions, namely, in gummata and in the lichenoid syphilide, the histological appearances are not to be differentiated from those of true tubercle. Moreover, Neumann asserts that giant cells are to be found in disseminated papules, in the pustular and lichenoid forms, in tubercula cutanea, and in subcutaneous gummata. He is not, however, always careful to show that he means cells of the Langhans type, a point of the utmost importance, inasmuch as the term giant has been applied to large cells with several nuclei, which are found in a variety of conditions, and which bear little or no resemblance to the Langhans type. He speaks, however, in his paragraph on giant cells in such a way as to lead us to infer that he always has in mind the Langhans type, and this is besides shown in some of his illustrations.

In pathological conditions other than syphilis, however, there is as yet,<sup>1</sup> so far as I am aware, no record of the discovery of Langhans cells or of the Wagner-Schüppel tubercle structure, with the exception of a case of Baumgarten, where these appearances were found in a sarcoma of the tibia, the subject of which finally died with generalized abdominal tumors, so that the case was regarded as unique.

The theory that in these cases we have to do with a mixed infection of syphilis and tuberculosis has not as yet received other support than that offered by the histological appearances. No tubercle bacillus has been found, and, so far as I am aware, there are no records of inoculation experiments besides those above mentioned, which proved negative. Still it must be admitted that this is merely negative evidence, and of value only if repeatedly verified.

It may be asked, of what significance in a doubtful cutaneous lesion, is the demonstration of Langhans cells and of the tubercular structure? With our present data we may say that we know of but two affections, syphilis and tuberculosis, where the cutaneous lesions may offer these appearances, but that in cases where the search for tubercle bacilli is not made, or proves negative, we are seldom justified in making a differential diagnosis from the histological structure alone.

<sup>1</sup> Since the above was written an article has appeared in the *Annales de Derm. et de Syph.*, by Bartholin, describing a peculiar affection termed *carcin.*, in which giant cells of the Langhans type were found by M. Durier.

## Clinical Department.

### A CASE OF PULMONARY ŒDEMA SECONDARY TO NEPHRITIS, COMPLICATING PREGNANCY.

BY FRANCIS W. ANTHONY, M.D., BRADFORD, MASS.

On May 29th, 1891, I first saw Mrs. A. P. W., pregnant for the third time, a period of thirteen years having intervened since a miscarriage had followed soon after the birth of her first child. During the present pregnancy she had been troubled with shortness of breath, and of late had suffered from several attacks of what she supposed to be asthma; her hands, feet and legs had been swollen, her hands so much so that she had been unable to close the fingers.

I found the patient cyanotic, with great dyspnoea, breathing sixty-five times a minute. Coarse râles could be heard across the room, and a hasty examination of the chest showed an alarming œdema of both lungs. The pulse was 150 and weak. Cardiac examination was negative—a decision that was subsequently confirmed. Legs, feet, hands and face were swollen and œdematous.

Dr. M. D. Clarke, and later Dr. William Cogswell, saw her in consultation. They agreed with me that the trouble was in all probability nephritic in origin, and that the prognosis was bad. I remained all night, using counter-irritation over the chest and to the lower extremities, alcoholic stimulation and hypodermic injections of sulphate of atropia and of nitro-glycerine. Twice in the course of the night, the patient appeared moribund, becoming semi-comatose, and the pulse very rapid and irregular; but at five in the morning she became easier and obtained a little natural sleep.

At ten, my previous consultants, with Dr. L. S. Smith, endorsed the treatment I had determined upon as soon as the condition improved—manual dilatation and delivery. I had in the course of the night obtained a small specimen of urine, and found that it was opaque with albumen, and that the sediment contained finely granular casts.

With the valued assistance of Drs. Clarke and Smith I began dilatation at 10.20, the patient being placed across the bed in an almost upright position, the orthopnea preventing any other. The os was unusually firm and resistant. I learned afterwards that her first labor extended from Thursday morning to Saturday night, and also that the os had been subjected to the cauterizer for some time within a few years. The patient had good pluck, and dilatation without anaesthesia was continued until, at 11.45, the tips of three fingers could be introduced. Anaesthesia was now necessary, and a more unpromising subject is rarely seen. Both the patient and her husband being fully informed of the circumstances of the case, chloroform was administered and the dilatation advanced as rapidly as possible, hypodermic injections of nitro-glycerine and of ether being administered meanwhile. At 12.10, after version, the child was delivered, some delay being caused in getting the arms as they went up above the head. The child, a female weighing four pounds, breathed after a little encouragement. Hot bottles were placed around the mother and hypodermic stimulation continued. She rallied well from the anæsthetic; and was left two hours later in the hands of a trained nurse.

The subsequent history of the case is uneventful. Several attacks of slight œdema rendered anxious the

first few days, and cardiac failure threatened twice. Inhalations of oxygen improved the color when cyanosis became marked, but the hypodermic injections of nitro-glycerine proved all the way to give the quickest and most lasting aid. Elaterium and saline cathartics, as well as diuretics, were brought into service, and the respirations decreased in frequency and became of better quality while the amount of albumen in the urine gradually diminished. The child, while weak, still lives and takes Rotch's mixture with increasing strength.

On June 19th, no albumen could be detected, and a careful examination of several slides June 21st failed to bring into view any casts. The patient is about the house, and calls herself well.

NOTE.—The child lived twenty-nine days, and died of exhaustion. The mother is to-day (October 1st) still in excellent health.

## Reports of Societies.

### AMERICAN ORTHOPEDIC ASSOCIATION.

The Fifth Annual Meeting of the American Orthopedic Association was held at the Arlington Hotel, September 22-25, 1891. Dr. A. B. JUDSON, President; Dr. JOHN RIDLON, Secretary.

#### FIRST DAY.

##### THE PRESIDENT'S ADDRESS.<sup>1</sup>

The President in his opening address, in referring to the limitation of the specialty, placed this as entirely voluntary, with an almost inexhaustible amount of work within these limits. He considered it well to recognize the lack of popular qualities of this department, not embracing brilliant and capital operations, and in a way, uninviting, inasmuch as the patients do not, as a rule, make perfect recoveries, but leave a residuum of disability.

It has its attractive features in dealing with realities, that is, with objective signs rather than in subjective symptoms, and in the following and aiding nature in her attempt to repair disease and give useful results.

He alluded to the death of Mr. Thomas, of Liverpool, and introduced Dr. A. J. STEELE, of St. Louis, who spoke of the

##### ORTHOPEDIC WORK OF THE LATE MR. THOMAS.

Dr. W. R. TOWNSEND, of New York, presented a paper on

##### UNIFORM NOMENCLATURE IN ORTHOPEDIC SURGERY,

in which he stated that in view of the success of the American Orthopedic Association, and the lead taken by America in this department, it seemed fitting for this Association to take the lead in defining what is Orthopedic Surgery, and establishing a uniform nomenclature. The aim of the latter is particularly to promote accuracy in properly classifying cases, which cannot be done by calling cases of synovitis, arthritis, or osteitis simply knee-joint disease, and this uniform division should be adopted by all hospitals. The pathology and symptoms of these various diseases are well enough understood, and there is no reason why, if these symptoms confuse, that some terms should not be agreed upon and adopted. We must all recognize one fault in not thoroughly recording our cases, and

<sup>1</sup> See page 318 of the *Journal*.

realize this in looking up hospital records. A uniform system would be greatly appreciated in such work.

It was moved by Dr. Vance and carried, that a committee be appointed to adopt some uniform nomenclature.

#### TWO CASES OF A PECULIAR TYPE OF PRIMARY CRURAL ASYMMETRY.

were presented by DR. H. L. TAYLOR, of New York.

The first, a woman twenty-three years of age, showed a difference of two inches in favor of the left side, measuring from the anterior inferior spine of the ilium to the internal malleolus. Measuring from the head of the tibia, the difference was one and one-eighth inches. In the second, a girl of fifteen, there was over an inch of shortening of the left leg, and in this one as well, over one-half was in the tibia. These cases present the peculiarity of a greater size and strength of the shorter side. In neither was there any evidence of affection of the nervous muscular or osseous system, beyond the unequal development. In neither did true lateral curvature exist.

#### A CASE OF SPINA BIFIDA WITH PARTIAL MOTOR AND SENSORY PARALYSIS. DOUBLE EQUINO-VARUS AND PURULENT BURSTITIS,

by DR. H. A. WILSON, of Philadelphia.

At the age of four years the conditions were shown by a photograph, to be that of a colored girl of robust appearance, an only child of healthy parents and was born at full term. There was no hereditary tendency.

The spina bifida was in the lumbosacral region, and the pedicle measured nine and one-half inches in circumference. The tumor was hard and dense except in one spot about a half of an inch in diameter, where the covering was extremely thin, and the contents oozed on pressure and when the child sobbed. There was incontinence of urine and involuntary evacuation from the bowels, owing to the paralysis of the sphincters of bowel and rectum.

All the flexor and extensor muscles of both legs below the knees were paralyzed, and electro-muscular contractility could scarcely be perceived. There was complete anesthesia of the right foot, ankle and calf, on the right side, which was present, although less marked, on the left. There was extreme double equino-varus, which firmly resisted manipulative correction. On both feet there were suppurating bursae under the distal extremities of the malleoli upon which the child stood in her attempts to assume the erect posture. At intervals of three and four weeks abscesses developed in the labia majora. Attempts made to arrest the suppurating bursitis by incision and application of chemical antiseptics, was followed by a persistent refusal of the incised parts to cicatrize, and with no perceptible cessation of the suppuration. This failure of incised wounds to heal, contraindicated surgical attempts at correction of the equino-varus, and mechanical efforts were followed by tumefaction and threatened suppuration at the points where pressure was necessary, and therefore also abandoned.

Preliminary puncture of the spina bifida, as recommended by James Morton, prior to injection, was followed by convulsions. The child is still living, in a hopeless condition.

#### CONGENITAL CLUB-FOOT, WITH ABSENCE OF GREAT TOE AND CONTIGUOUS BONES OF THE INSTEP,

by DR. T. M. L. CHRISTIE, of New York.

The description of the foot, and the result of the treatment, were presented by the writer. The case was one of congenital equino-varus, with absence, from arrest of growth, of first row of phalanges, shaft of first metatarsal and internal cuneiform bones, and of the two tibial and other three muscles attached here. The scaphoid was not fully formed. The treatment resulted in cure of the talipes, with acquisition of symmetrical gait in six months. Figures from photographs were used to illustrate the paper.

DR. WM. E. WIRT reported a

#### CASE OF DOUBLE CLUB-FOOT, DOUBLE CLUB-HAND, AND MULTIPLE DEFORMITIES,

which he stated was similar to the one recently reported by Dr. Gibney, but of a severer grade. There was double club foot and hand, rudimentary joints at the hips, knees, shoulders, elbows and wrists, and contraction of the plantar fascia. The motion at these joints was slight, and seemed limited by ligamentous and bony structures. There was the history of fright of the mother at the fourth month, and difficult labor with breech presentation.

In the paper

#### THE AFTER-TREATMENT OF EXCISION OF THE KNEE-JOINT,

DR. JOHN C. SCHAPPS, of Brooklyn, reported two cases cured without fracture by means of the osteoclast and brace. In operating, it is important to bring the vertical axis of the two bones in a vertical line, so that the weight is transmitted vertically. In operating by excision, if all the diseased bone is removed, the limb usually soon becomes firm. Mechanical treatment should be continued at least two years.

#### GONORRHEAL RHEUMATISM AND ITS TREATMENT, PRIMARY AND SECONDARY,

by MR. B. E. BRODHURST, of Loudon, was read by the secretary.

In this, the varieties and pathology of the affection was considered. While effusion is rapid, and pain severe, suppuration never occurs. Several joints are often attacked simultaneously, and one frequently remains impaired. The treatment in fresh cases consists of external applications, and the inunction of mercury was advised. In old cases there are adhesions and usually some flexion. The treatment is to break up these adhesions by force, used in the direction of extension, which will not cause injury. The writer stated that he had operated in over a thousand cases of this affection, and with no bad results.

DR. E. G. BRACKETT, of Boston, read a paper on

#### ATROPHY IN JOINT-DISEASE<sup>2</sup>

in which the different theories regarding the causation of this, were considered. That having had the most general acceptance is the reflex theory of Vulpian, which supposed it to be the direct result of the irritation of the diseased joint, on the nutrition through the nervous system. The theory is inadequate as it does not explain the large number of cases. There is no constant relation between the severity or duration of the disease, and the degree of the atrophy, and this instead of being confined to the part affected, is distributed over the whole limb. The lack of development, which appears later, is subject to the same distribution and influence. The amount of both wasting

<sup>2</sup> To appear in full in an early issue of the Journal.

and the late atrophy is more dependent on the amount of use, and bears a relation to this. The results of a series of observations to illustrate this were given.

DR. A. M. PHELPS, of New York, in a paper entitled,

SOME LATERAL TRACTION FIXATION HIP SPLINTS, advocated the following principles: that extension and fixation are necessary; that spasm is always present, and this involves the adductors and glutei. To overcome the spasm of these, lateral traction is necessary. That ankylosis is the result of pathological causes, not of prolonged fixation. The patient should never be allowed to step on a splint, but should have rest in bed until deformity and symptoms have disappeared, then use crutches and high sole. The joint should remain fixed, and passive motion prohibited until cured. In children under three and a half years of age, the plaster-of-Paris portable bed should be employed.

The following papers were read by title:

ON THE BEST MEANS OF PREVENTING A LOOSE JOINT OR DANGLING LIMB, AFTER RESECTION AT THE SHOULDER-JOINT, WITH AN ILLUSTRATIVE CASE,

by DR. W. R. WHITEHEAD, of Denver.

ON THE USE OF THE WRENCH IN THE TREATMENT OF CLUB-FOOT,

by MR. ROBERT JONES, of Liverpool.

OPERATION ON THE CONCAVE SURFACE IN TALIPES EQUINO-VARUS,

by DR. R. E. MCKENZIE.

THE DIAGNOSTIC AND PROGNOSTIC VALUE OF HIGH TEMPERATURE IN CHRONIC JOINT DISEASE,

by DR. ROBERT W. LOVETT.

ON THE TESTS FOR RECOVERY FROM JOINT DISEASE,

by MR. ROBERT JONES.

APPARATUS FOR MAKING TRACTION,

by DR. WM. E. WIRT.

#### SECOND DAY.

The first paper was presented by DR. JOHN RIDLON, of New York, on

SYPHILITIC POTT'S DISEASE IN CHILDREN.

The writer referred to the reluctance, which, a few years ago, he found among medical men to accept this affection as an independent disease. Since that time he has had opportunity to further observe the subject, and is convinced of the existence of this disease. It is usually hereditary, but its presence does not necessarily communicate either to the parents, as it may have been transmitted from the grandparents. The onset and development is very slow, except in the spine, where, from its location, its existence is not manifested until considerable progress has been made, and thus its onset here may apparently be rapid. The abscesses usually disappears when the mercurial treatment is pushed. Spondylitis under three and a half years of age, and existing with other joint affection, he considers to be very probably specific. The most common accompaniment is other joint affections; the least common specific manifestation is skin lesion. The

treatment is mechanical and medicinal, the latter, mercury and iodide of potash.

DR. ROSWELL PARK presented a paper entitled

A STUDY OF ATROPHIES,

which was in the main historical, the principal monographs, on which it was based, extending back to the early part of the present century, among the authors quoted being Curling, Bennet, Verneuil, and Ollier and his pupils. Great importance was given to the work of the latter. He established that the common cause of hypertrophy of bone is irritation. The causes of atrophy he divided into those by which there was produced destruction of tissue which concerns or favors their growth; and gradual failure in the evolution of such tissue; mutilations of bone almost always produce arrest of development, not alone in the bone injured, but in the parallel bones. Ollier laid particular stress on the effect of functional inaction or atrophic elongation. Growth is of two kinds, laterally and longitudinally, and when the one is interfered with, there is an apparent elongation, seen sometimes in the long bones. The occurrence is important, rather pathologically, than clinically. The writer spoke in high praise of this work of Ollier, with the views of whom, the paper had particular reference.

DR. T. HALSTED MYERS, of New York, read a paper on

POTT'S DISEASE AND PREGNANCY,

in which he referred to the diminished size of the abdominal cavity in vertebral disease, also to the local hyperemic condition during this state, and the necessary detrimental influence of this on a vertebral disease. An examination of the records of Maternity Hospital showed a relatively high mortality when this disease existed. In seven cases, in which the disease developed during pregnancy, three died and three were left paraplegic. The practical question is the effect of the pregnant state on this disease. The conclusions are, that in cured cases no harm is done, and the disease is not rekindled; but in uncured cases, the danger is considerable, and the writer would advocate an early termination of the pregnancy.

A paper on

PARAPLEGIA IN POTT'S DISEASE,

was read by DR. E. G. BRACKETT, of Boston.

One method of double extension with fixation was considered, and the results, with cases, given. The conclusions were: That recovery may be looked for even after its persistence for many months, and when sensation and the spinetters are involved, that the treatment of extension and fixation is often attended by decided improvement and should be given a thorough trial; that the most careful attention is necessary to the details in securing a well-adapted support to the back and the continuous and even extension; that the rest should be persisted in, not only until all evidence of disease has disappeared, but until the return of the use of the limb is well established.

DR. ALBERT HOFFA, of Würzburg, presented a paper entitled

PRESSURE-MYELITIS IN POTT'S DISEASE.

The affection is the result of the tubercular process in the vertebrae, and is for a long time confined to the epidural space, and is essentially a pachymeningitis. Finally the process may pass through the dura, and

the cord itself then becomes involved. At one stage there may be an oedema, later the membranes become thickened. The first symptoms are of functional disturbance of the cord, and are due to the pressure and from an anæmia from this pressure interfering with the natural flow of lymph. When the pathological process has extended through the membranes and involved the cord, the condition is a true sclerosis, and may result in the degeneration of the nerves.

The object of treatment should be to confine the exudation to the smallest area possible. This is best accomplished by rest and extension. It is difficult to reach the epidural space by operation, and the results are not encouraging. The writer doubted if the operation had a brilliant future, and thought it should be confined to those cases in which the disease involves the articular processes as well as the bodies of the vertebrae.

#### ABSCESSSES IN POTT'S DISEASE.

DR. W. R. TOWNSEND, of New York, read a paper in which he considered the method of treating these abscesses, and a valuable series of statistics were given in connection. If all those cases treated by the expectant method did well, the wisest course would be evident; but while some of these improve under this method, in others the general health fails, and the result is not satisfactory. If, on the other hand, we could be sure that by operation the evacuation would be complete, and all residuum cleared away the best method would be equally evident, but in a certain number of cases, infection takes place.

In 19 cases of abscess treated expectantly, 11 disappeared, three opened, four increased, one remained *in statu quo*. In 14 operation cases, 11 became infected later, and three did well. In 21 cases allowed to open spontaneously, 15 did well, and six badly. The writer advocated the expectant treatment so long as the patient was doing well. Resorption takes place more often than is usually considered, and can be helped by use of the aspirator, and the injection of iodoform. When the health fails under this plan, evacuation should be resorted to. Fixation in all cases is essential.

#### BILATERAL LUMBAR ABSCESS, WITH CASE,

by DR. JAMES K. YOUNG, of Philadelphia.

Dr. Young presented the history and photographs of a case which illustrated the results of bilateral lumbar abscess accompanying Pott's disease in a child aged four years. One abscess was aspirated twice, the other was allowed to break spontaneously; and with strict antiseptic dressings the child has now recovered.

He referred to the influence of the seat of the lesion and the importance of the fascias in determining the course and exit of spinal abscesses generally, and particularly of the psoas fascia and the lumbar fascia in lumbar abscess. If the abscesses find exit upon the surface of the vertebra anterior to the attachment of the psoas fascia, it will terminate by burrowing along the great vessels or become an iliac abscess; if it open posterior to the psoas sheath, it will burrow backward and laterally along the middle layer of the lumbar fascia, separating the quadratus lumborum from the internal oblique, through the internal oblique and between the external oblique and latissimus dorsi to appear at the outer border of the erector spinal muscles. This was the course in the case presented; and he suggested the division of lumbar abscesses into external

and internal, their relation to the sheath of the psoas fascia and the anterior layer of the lumbar fascia determining their position.

#### THE BENIGN COURSE OF ABSCESSSES IN POTT'S DISEASE UNDER EFFICIENT MECHANICAL TREATMENT.

DR. NEWTON M. SHAFFER gave by abstract his views of this treatment. It presupposes the most careful mechanical treatment, and his remarks applied only to the large spinal abscesses, where the health had already suffered, and where the endurance of an operation is in question. His largest record of deaths in spinal abscess has been after incision in such cases, and as these often do so well if true mechanical support is given, that he would advocate this course. Cases were cited illustrating favorable results with this method.

DR. AP MORGAN VANCE, in his paper on

#### THE ASPIRATOR IN ORTHOPEDIC PRACTICE,

advocated the withdrawal of the fluid by the needle, and the application of firm pressure. Under this method the fluid soon becomes serous, and the cavity finally ceases to refill. Occasionally it becomes caseous and will not pass the needle.

In the discussion of these papers Mr. Howard Marsh stated that in England, the feeling was steadily and strongly becoming in favor of operating on these abscesses early and freely. He had tried the various methods, of letting them alone, of aspirating, and of freely incising, and prefers the latter. By attention to asepsis, and the use of pressure, the danger is not great, and he would say that about four or five per cent. only, of the cases thus treated did not do well.

He also stated that he felt that the presence of the abscess tends to continue the disease, and for this reason, it is good practice to evacuate early.

DR. HENRY LING TAYLOR read a paper on

#### THE VALUE OF MECHANICAL TREATMENT IN OLD AND NEGLECTED CASES OF POTT'S DISEASE.

There is a ten-fold object in the mechanical treatment of Pott's disease, to provide rest and fixation to the spine, and to promote the hygienic conditions, and to as far as possible, prevent or rectify the deformity. The course of the disease is often extremely slow, and in many old and deformed cases, the knuckle keeps on slowly increasing, or after many years of immunity, the disease is lighted up by a strain and fall. Even these old and desperate cases, both in children and adults, often respond kindly to mechanical treatment. The figure and carriage may often be improved, and when this is possible, increase may often be prevented, and health restored by careful mechanical treatment.

(To be continued.)

## ASSOCIATION OF AMERICAN PHYSICIANS.

THE SIXTH ANNUAL MEETING, HELD IN WASHINGTON, SEPT. 22-25, 1891.

(Concluded from No. 17, page 444.)

## FOURTH DAY.

THE CONDITIONS AND PROSPECTS OF THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE, AND ITS INDEX-CATALOGUE.<sup>1</sup>

DR. JOHN S. BILLINGS, of Washington, presented a paper on the above subject.

## SEQUEL TO A CASE OF SLOW PULSE,

by DR. D. W. PRENTISS, of Washington.

This report completed a case of slow pulse previously reported to the Association. The patient was brought before the Association for examination both last year and the year before. The man, aged fifty-three years, had a pulse ranging from 11 per minute to 40 per minute for two years and was the subject of frequent attacks of syncope. No disease of heart or other organs could be discovered. The last reports of the case was made in May, 1890. From May 24 to July 2, 1890, the symptoms continued as mentioned, the pulse ranging from 13 to 21 per minute, with frequent spells of syncope; towards the last almost constant delirium, and for the last few days he wandered restlessly about the house in constant fear of being shot.

July 4, 1890. More delirious and restless than usual; thought several parties were trying to kill him. Screamed with terror "murder," "fire," until the neighborhood was alarmed. Was induced to lie down on the bed. His wife left him for a few minutes and on returning found him dead.

**Autopsy**—Autopsy was made by DR. R. T. Edes, seventeen hours after death. Heart rather large and firm, lungs being well dilated, it is probable that no more than the normal surface of the heart came in contact with the thoracic wall. Neither the aorta nor the coronary arteries were atheromatous. Brain and upper portion of spinal cord healthy to gross appearance. On the right side, the upper cervical ganglion of the sympathetic, the lower cervical ganglion, a portion of the thoracic sympathetic, a portion of the splanchnic at semi-lunar ganglion were removed. On the left side the same portions, except the upper ganglion and the thoracic sympathetic. All were normal to the naked eye. On dissection of the heart, the left pneumogastric appeared normal until the region was reached where it bends under the arch of the aorta to give off the recurrent laryngeal. Here several of the strands appeared somewhat less clearly defined through the surrounding connective tissue, which, at this point,

was more strongly adherent. There were fusiform enlargements of the several cords. One of these was on a cord going downward to form the œsophageal plexus; others were on the bend of the recurrent laryngeal just below the artery. At this point the recurrent laryngeal gives off branches which connect with the cardiac plexus. The muscular substance of the heart was firm and not fatty, walls of both ventricles thickened, those of the right perhaps more in proportion to its usual thickness. The fusiform enlargements at the point of separation of the cardiac branches from the recurrent laryngeal were so much injured in the process of dissection that the microscopic examination disclosed nothing. The other cords and ganglia were normal. The intrinsic cardiac ganglia were not found. The pneumogastric nucleus in the medulla showed no lesion. The medulla as a whole appeared congested.

DR. PEPPER thought the report of Dr. Edes might be considered a negative one.

DR. EDES thought that the finding of the enlargements rendered the report not entirely negative.

DR. PEPPER alluded to the fact that nearly all the members who commented upon the case last year thought the patient was the subject of arterio-sclerosis, the radials being hard and of increased tension, yet the autopsy revealed no material changes in the coats of the vessels.

DR. WELCH stated that similar fusiform enlargements are present normally on the cardiac nerves, and they are inconstant in their distribution, and it is possible that the conditions described by Dr. Edes might correspond to some normal arrangement of the enlargements on the cardiac nerves.

## EXHIBITION OF SPECIMENS OF HAIR, SHOWING CHANGE OF COLOR FROM INTERNAL USE OF PILOCARPINE AND JABORANDI,

by DR. D. W. PRENTISS, of Washington.

The first case was that of a young lady who up to twenty-five years of age had light blonde hair. She was treated with hypodermic injections of pilocarpine, one-sixth of a grain two or three times a week, for uræmia from suppression of urine. In two weeks time her hair was distinctly brown, and in six weeks it was black. This was ten years ago. The color of the hair at this time is still black. Another case was an old lady suffering from interstitial nephritis; her hair was quite white. The principal symptom that gave her distress was itching of the skin from dryness. For relief of this, fluid extract of jaborandi was given. This gave relief for nearly a year. In the course of eight or nine months her eyebrows were black, and after that her hair in patches over her head became black, and new hair was growing all over the scalp. Before this new growth became of any length she died.

## GRAVE FORMS OF PURPURA HÆMORRHAGICA,

by DR. J. H. MUSSER, of Philadelphia.

Dr. Musser referred to the classification in use at the present time of idiopathic and symptomatic purpura; the former including simple rheumatic and malignant forms, or peliosis rheumatica and morbus maculosus verrillioii; the symptomatic varieties including scurvy were also detailed. Reference was also made to the monograph of William Koch, recently published, who claims that scurvy and various forms of purpura are identical and of infectious origin. Dr. Musser was not able to see, viewing the cases from a

<sup>1</sup> See page 341 of the Journal.

clinical standpoint, any justification of the infectious nature of these diseases or even their affinity. Koch himself, did not prove absolutely the bacterial origin, nor define the micro-organism that was the cause of the disease. The observations quoted from Fagge, were referred to as the bacterial origin.

Reference was made to the relation of purpura symptomatically to affections like urticaria and its relations to rheumatism. Five cases were reported by Dr. Musser, illustrating grave forms of this disease. The first case reported was that of a woman who suffered from hæmatemesis for several months. Its origin was obscure, and, in fact, could not be determined until further development of the case. After a period of some failing health, suddenly purpura developed. Subcutaneous hæmorrhages first were seen, and then hæmorrhages of the mucous membrane. The patient died suddenly with symptoms of internal hæmorrhage: and at the autopsy the death was found to be due to large hæmorrhage behind the retro-peritoneal space, and in the œsophagus a small pin-point communication with the enlarged veins was found, which showed the source of hæmorrhage. The second case was also one of excessive gastric and intestinal hæmorrhage, and general subcutaneous hæmorrhages with grave symptoms. The boy recovered. The third and fourth cases presented many symptoms in common. With the development of purpura, with severe joint complications, in each case, excessive œdema in different portions of the body, particularly the extremities and eyelids, was observed. In the first case was also œdema of the uvula, which led subsequently to sloughing and complete destruction of it. The patient had some fever, and there was a question whether this uvula inflammation was not of deep origin. He recovered after a tardy convalescence, although, at the time, recovery was rendered doubtful by the presence of large murmurs in both valve areas of the left heart, which appeared to indicate the possibility of an ulcerative endocarditis. No doubt these murmurs were due to old valve lesions. In addition to the symptoms purpura and œdema in the second case, with severe joint symptoms, there was also œdema of the uvula, with gangrene and sloughing, as well as large sloughs of the skin of the scrotum and penis. This patient recovered. In both the blood was examined carefully. At no time was there much reduction in the red cells. In one there was a notable reduction in the hæmoglobin, falling as low as twenty-seven per cent. at the height of the disease. As convalescence became established the hæmoglobin gradually increased. Bacteriological studies were made of the blood, but without results of any value. The fifth case was most acute in its course. The patient, a girl of twenty-three years of age, was suddenly seized with severe hæmorrhage from the stomach followed by intestinal hæmorrhage. One day, after the onset of the gastric hæmorrhage, subcutaneous hæmorrhages took place and joint symptoms arose. The symptoms were attended with severe headache and marked hysteria. On the fifth day a severe conjunctivitis and iritis developed. The temperature on this day, which had previously been about  $104^{\circ}$ , increased, and with the increase in temperature, delirium, followed by coma, ensued. The hyperpyrexia became more and more pronounced, and death ensued at the end of twenty-four hours with a temperature of  $108^{\circ}$ .

Dr. PEPPER related two grave cases seen by him

last spring in school-children of about eleven and thirteen years. There were extensive hæmorrhages in both cases, with sloughing. In both cases complete destruction of vision in the left eye occurred on filling of the globe of the eye with blood. Another case was in the person of a lady of about thirty. There was the characteristic eruption, then sudden hyperpyrexia, ( $105^{\circ}$  to  $106^{\circ}$ ), extensive outbreaks of petichiae, and the largest cutaneous hæmorrhages ever seen by Dr. Pepper. There was immediate subsidence of fever with absorption and cure without sequelæ.

Dr. D. W. PRENTISS spoke of an exceptionally grave case which he had presented to the Association last year. The case was marked with periodic exacerbations. The patient had violent symptoms of purpura with joint affections and with intense suffering. He would recover from an attack in ten to fourteen days, and in about six weeks the symptoms would recur with great violence. He had hæmorrhages in different portions of the body, — from the bowels, from the bladder, under the skin, although never from the lungs. Sloughing occurred subsequent to hæmorrhage in the skin of the abdomen and that of the prepuce. He had symptoms simulating peritonitis and enteritis. Two members of this Association suggested phosphorus as the best treatment. Up to that time arsenic had been used. He was put upon phosphorus. The relapses occurred with lengthening intervals until they stopped altogether and the boy entirely recovered.

Dr. GRAHAM, of Toronto, said that Dr. Jacobi and himself had suggested the phosphorus. He uses it in the form of phosphide of zinc. The only fatal case under his observation was one in which death took place as the result of an enormous clot that formed in the bladder, distending it so that the fundus reached the umbilicus. In this case phosphorus was not used.

The following officers were elected: President, Dr. Henry M. Lyman, of Chicago; Vice-President, Dr. George Ross, of Montreal; Secretary, Dr. Henry Hun, of Albany; Treasurer, Dr. W. W. Johnston, of Washington, D. C.; Recorder, Dr. I. Minis Hays, of Philadelphia.

#### NEW YORK COUNTY MEDICAL ASSOCIATION.

At a meeting held October 19th, Dr. FREDERIC S. DENNIS exhibited a remarkable case of

#### NON-TRAUMATIC ACUTE SUPPURATION — OSTEOMYELITIS.

The disease was located in the tibia, and a favorable result, saving both the life of the patient and the limb, was achieved by making an incision four inches long, cutting down into the medullary cavity of the bone, and removing all the pus and diseased tissue. In this case, the presence of the cause of the septic intoxication, the microbe designated *staphylococcus pyrogenes aureus*, was demonstrated by Dr. E. K. Dunham at the Carnegie Laboratory, and pure cultures of the microbe were obtained from the pus taken from the diseased limb. Specimens of both the microbes and the cultures were shown.

Dr. Dennis also presented several other interesting surgical cases, among which was a case of

#### NON-TRAUMATIC ACUTE SUPPURATIVE ARTHRITIS OF THE KNEE-JOINT,

which was found to be of gonorrhœal origin. Gono-

c cci having been demonstrated in pus taken from the joint, it was decided not to open the latter widely, but to evacuate the pus, and keep the parts fixed by Buck's extension apparatus. Internally, large doses of iodide of potassium were given, and the result was very satisfactory. At the time the case was shown there was still considerable enlargement of the knee, but there was good motion in the joint.

Another case was that of a patient who, four years ago, had an

#### ANEURISM OF THE RIGHT POPLITEAL ARTERY.

which was cured by Dr. Dennis by means of compression with an Esmarch bandage, for an hour and a half under ether. Some two years afterwards an aneurism of the left iliac artery developed, and more recently the sac seemed to have burst, producing enormous distention of the limb, the swelling extending down to below the knee. The existing condition of affairs called for some active measure, and Dr. Dennis said he had not yet decided whether to amputate at the hip-joint or perform laparotomy and ligate the iliac artery.

### Recent Literature.

*A Text-Book of Physiology.* By M. FOSTER. Fifth Edition. Revised. Part IV. London and New York: Macmillan & Co. 1891.

This part completes the new edition of "Foster," the appearance of which was noted in this journal at the time. The previous parts have shown a most painstaking care in bringing the subject fully up to date. The number of pages has grown from 770 to 1356 and of this increase nearly one-half may be credited to the discussion of the central nervous system. The same admirable spirit that has hitherto characterized this text-book is manifested in this last edition which is still easily the leading English book on the subject.

The part before us discusses the special senses, reproduction, and "the chemical basis of the animal body." It is practically a reprint of the corresponding portions of the previous edition although coming out eight months after the preceding part. As to the special senses and reproduction this reprinting does little harm since comparatively slight progress has been made in these subjects. It is, however, a serious defect to have the "appendix" a literal reproduction of the physiological chemistry of the edition of 1883. This defect is lessened for the teacher and pupil by the recent appearance of Halliburton's book on this subject and the regret of the reader is modified by the hope of the author that a new edition may begin to appear this autumn. It would be a great advantage if some arrangement could be made to insure the appearance of the parts with more promptness than has been shown in getting out the present edition.

We would also urge that references should be made to the more important investigations. The author gave up this practice because he felt that many students derived no benefit from the presentation of authorities which they either neglected or learned by heart. On the other hand, students seem to fall into the error of attributing everything to Foster which is not only too great a burden for that genial author but also unfair to the patient investigator who often gets no other recognition.

## THE BOSTON Medical and Surgical Journal.

THURSDAY, OCTOBER 29, 1891.

*A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.*

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,  
283 WASHINGTON STREET, BOSTON, MASS.

### THE VISION OF RAILWAY AND NAVAL EMPLOYEES.

In the Section of Ophthalmology at the annual meeting of the British Medical Association, held in Bournemouth last July, a discussion took place on the vision of railway employees. The papers read and remarks made were so eminently practical that we quote the following from the reports.

Mr. Beaumont, surgeon to the Bath Eye Infirmary, said: "The method of testing the vision of railway officials appears to be insufficient and inaccurate. This opinion is founded on a knowledge of the method adopted by the railway companies, and confirmed by practical experience gained by attending many railway servants suffering from refractive and pathological anomalies of vision." He gives several cases of extreme defective vision passed by officials, which would very properly frighten the passengers on a train if they knew these men were driving their engine. He says very forcibly, "It appears to be useless to attempt to get any voluntary reform from the railway companies"; and insisted that the tests should always be applied by qualified medical men, laying down the standards which should govern their decision.

Mr. McHardy, professor of ophthalmology and ophthalmic surgeon at King's College, London, gave a very practical paper. He said: "Before this audience I may be excused for merely stating as a truism that Holmgren's test for the detection of subnormal color perception, conducted by means of specially selected skeins of variously colored wool, practised in precise accordance with the directions clearly laid down by its author, discourages deceit, and may expose wilful imposture. . . .

"Practical tests (so called) to detect subnormal color perception, etc., by questioning men as to the color or significance of signal lamps or signals, are absolutely impracticable, and must prove misleading and ruinously costly in application, besides inviting and encouraging deception and discontent." After very clearly showing the practical results from defective vision, he

adds: "I hope that with a minimum use of technicalities I have stated sufficient to show that the efficient control of railway men's eyesight can alone be conducted by ophthalmic experts. . . . This was recognized by our revered master, Professor Donders, who in December, 1879, wrote: 'I most willingly testify that it is my full conviction that only medical experts—ophthalmic surgeons—should be employed in testing color perception and acuteness of vision.' From a long letter from Professor Holmgren, dated December, 1879, to Dr. Joy Jeffries, who has so usefully identified himself with this subject in the United States, I deem the following especially worthy of record: 'In Sweden, railway surgeons have been practically and specially instructed *de visu* by me, and we have every reason to be satisfied with this. There are many cases which no railroad official can detect or decide, and not even the ordinary railway surgeon can be sure of. . . . The time has long passed for knowing everything; division of labor is a law of our times, proving its advance.'"

Mr. McHardy goes on to say: "I have been led to supplement my knowledge and experience as an oculist by personal, practical observation from the foot-plate of ordinary express, passenger and goods locomotives, in all kinds of weather and all states of atmosphere. . . . I have gained experience also, from direct experiment in the most practical way, as to the differential visibility of railway signals to eyes with normal focus, with varying degrees of longsightedness, shortsightedness, and astigmatism; for, having become well acquainted with the signals, etc., on some eighty miles of railroad, I never travel with my eyes handicapped to known degrees by glasses. A comparison of the diaries of my foot-plate experiences shows that as nearly as possible the recognizability of railway semaphore signals is in distinct accord with the observer's degree of acuteness of vision as measured by Snellen's standard. . . . I am mindful of the extremely imperfect and dangerous manner in which government departments here attempt to control eyesight while professing to be strict. I refer, of course, to the authorities responsible for the eyesight of the *personnel* of the Royal and Mercantile Navies of this country."

Mr. George Mackay, assistant ophthalmic surgeon to the Eye Dispensary of Edinburgh, reports in detail with reference to examinations of employees on four separate railroads. His summary is this: "I have given here, as briefly as possible, the method at present in use for the determination of the visual acuteness of 4,160 firemen and engine-drivers, more than 2,000 guards, and over 2,600 signalmen employed in 3,056 miles of railway. It will be admitted that the visual power of the greater portion of these men is very inadequately tested, and I hope that the outcome of our meeting to-day may be the appointment of a committee to consider the best recommendations which ophthalmic surgeons can make to the railway managers with a view to a reformation."

Dr. W. A. Brailley, ophthalmic surgeon to Guy's

Hospital, being called upon by the chair, said, that a Committee appointed by the International Medical Congress of London, 1881, "having the great advantage of the services of the distinguished Professor Donders as President" reported proposed standards of requirement which the Congress voted on in approval. The Ophthalmological Society of the United Kingdom subsequently appointed a committee, on which was Dr. Brailley, who interviewed the Secretary to the Board of Trade. He adds: "True, we met with no active opposition to our proposal, but official immobility was too much for us, and no practical good resulted."

The following resolution proposed by the President was adopted, "That a committee, with power to add to its number, be appointed to promote the efficient control of railway servants' eyesight in the United Kingdom, and to report thereon from time to time to the British Medical Association; that such committee be designated the 'Committee on the Control of Railway Servants' Eyesight.'" Ten well-known ophthalmic surgeons were appointed, who had identified themselves with this movement. Some doubt was expressed in the Section as to whether their committee should await the report of the special committee of the Royal Society asked for by the Government more than a year ago.

An editorial in the *British Medical Journal* of August 29th, advocates most strongly the results and action of the Section of the general Society, and shows the absurdity of the present tests as used on the railroads, etc. One sentence we quote, as it is applicable here as in Great Britain: "Unfortunately, when this subject is broached, there are certain medical men who, instead of advancing their views where they can be adequately discussed, take the opportunity of writing a signed letter to the lay press. Railway directors are thus led to believe that there is a real difference of opinion among authorities as to the proper tests to be employed, and not unnaturally delay to take any action; at the present time, moreover, they have a further excuse for delay in the fact that a committee of the Royal Society has the whole question under consideration."

Our readers may not know or recall the fact that from silly articles in the press a considerable stir on the subject was made last year in London, resulting in Mr. R. Burdenell Carter, a distinguished ophthalmic surgeon, being called upon as an expert to address the Society of Arts in London, in consequence of which he was asked to lecture at the Royal Institution on "Color-Vision and Color-Blindness," which he did May 9th, before a very distinguished audience. It finally came before the Royal Society, where the practical experts were most fully sustained. The Government followed this up with a request for a report on defective vision and color sense, on which their action would be based. That report is still awaited from the committee, which consists of the President, Sir G. G. Stokes, Lord Rayleigh, Professor Michael Foster, Captain Abney, Francis Galtier, Professor Church,

Dr. Wm. Pole, and Mr. R. Burdenell Carter, whose names guarantee practical and scientific investigation, and recommendations independent of "ignorance, prejudice and pecuniary considerations," that seem to constantly block all attempts to control defective vision on land and sea for the saving of life and protection of property.

#### ON THE TREATMENT OF PERITYPHLITIS.

JUMON in *Médecine Moderne* somewhat exhaustively reviews the treatment of perityphlitis. The management of this disease, he says, has been greatly modified of late years; it has become chiefly surgical. But it is no less true that at the onset it should be purely medical. Antiphlogistics, refrigerants and opiates should be employed; everything which excites intestinal action should be avoided—even the saline laxatives and lavements so much vaunted by certain authorities. On this point we remark there is anything but agreement, though all admit that active catharsis is to be deprecated.

At Nothnagel's clinic, in recent cases and during the first two or three days, much reliance is placed on leeches and bladders of ice. As many as eight or ten leeches are applied over the seat of pain and swelling, and the oozing of blood is encouraged by warm fomentations after the leeches drop off. The result of this treatment appears to be encouraging. After the bleeding ceases, the ice-bladder is applied. If this is not well borne, warm poultices or fomentations are substituted. Later on, the abdomen is painted with a mixture of iodoform-collodion, tincture of iodine, and tincture of galls, of each equal parts, and frictions with green soap are resorted to, if absorption of the exudation is slow. Quinine and suitable nourishment is given; opium is prescribed in some, though not in all cases. If the pain is intense, hypodermic injections of morphine are employed. When the inflammation is subdued, and during the period of amelioration, laxative lavements are employed in cases where the bowels are confined. If there still remains sensibility to pressure and a slight resistance, an occasional massage with green soap is ordered.

Vollert cites a case occurring in Nothnagel's clinic where, despite symptoms of the greatest gravity, the patient recovered under purely medical treatment. It was a case of perityphlitis with diffuse peritonitis complicated with pyæmia. The temperature went up on several occasions to 15.5° C. (114° F.); the patient had frequent chills, and the spleen was tumefied. Quinine, salicylate of soda, and antipyrine were given to combat the fever. The patient got completely well at the end of five months.

Out of thirty-four cases, three were fatal. Death in the first patient was due to perforation of the appendix; in the second, to ulcerated medullary cancer of the cæcum; in the third, to intestinal concretions with perforation of the appendix, diffuse peritonitis, followed by perforation of the diaphragm, ulceration

of the pleura, and hyperpneumothorax of the right side.

What are the indications for operating in perityphlitis? Jumon, in the article aforesaid, replies that there should be no hesitation as soon as there is certainty of the existence of an abscess. An operation ought not to be thought of during the first few days. He has, in fact, known cases in which the most acute symptoms—high fever and violent pain in the ileo-cæcal region—have accompanied the development of a voluminous tumor, and yet all these inflammatory phenomena have disappeared in a few days under an "antiphlogistic" treatment, and even expectancy. Vollert, chief of Nothnagel's clinic, also agrees with Jumon that an early operation is seldom called for.

On the other hand, if the exudation tends to become chronic, and if there is suppuration with fever, a surgical operation is demanded. An early operation, moreover, is not contraindicated if there is certainty of the existence of an abscess; also, if there exists an acute peritonitis by perforation, even before the formation of adhesions, as here a laparotomy would be the last chance of life for the patient.

To these indications, J. Israël adds another: A laparotomy is indicated in recent cases of perityphlitis when there are grave symptoms, such as: frequency of the pulse with normal or sub-normal temperature, pallor or cyanosis, vomitings, in short, when there is aggravation of the general and local state, although there may be no adhesions, and the presence of an abscess may not be demonstrated.

The most favorable cases for operation, according to Jumon, are those in which the exudation is circumscribed, encapsulated. But it will not do to forget that purulent collections of considerable size have disappeared under the influence of medical treatment alone. If there exists already a general peritonitis, the prognosis will be always unfavorable whether an operation be performed or not.

In cases of perforation of the appendix, there should be complete resection of the latter if there are no obstacles in the way, due to adhesions to the cæcum, mesentery, or neighboring intestinal coils. It is certain that many cases get well promptly after resection of the appendix, and that the danger of relapses is prevented by the operation. This fact has led many surgeons in this country to prefer an early laparotomy which, if successful, is followed by removal of the cause and prompt recovery, with no possibility of a return, to the doubt, anxiety and risk attending a purely medical treatment. But this subject was so fully discussed in all its bearings at the last meeting of the Massachusetts Medical Society<sup>1</sup> that we need only advise a careful reading of the report of that meeting. Twenty or thirty years ago the frequency of appendicitis with subsequent fatal peritonitis, was pointed out by Dr. J. B. S. Jackson. Operative interference was not then thought of, and treatment halted between first, leeching and mercury; second, opium.

<sup>1</sup> See JOURNAL, vol. cxxv, p. 36.

## MEDICAL NOTES.

**THE VIRCHOW MEDAL.**—It is said that the medal presented to Professor Virchow, at his recent jubilee, measures 118 millimetres in diameter, and is made from eighteen-carat gold. The front of the medal bears a bust representation of Virchow in relief. The back is adorned with an heraldic design, the allegorical figures of medicine and pathology; microscopes, books, skulls, and an Egyptian mummy.

**MEDICAL CASES AT AN EXHIBITION.**—The medical committee of the World's Fair may know what to expect from the experience of the last Paris Exhibition, where, according to *Figaro*, 732 female visitors had attacks of hysterics, whilst only 197 fainted. There were no less than 11 deaths in the Exhibition, and, strange to say, three births. Only 243 thefts were reported; but the police restored no less than 305 lost children to their friends.

**NEW JERSEY MEDICAL EXAMINERS.**—The first annual report of the New Jersey State Board of Medical Examiners shows that the Board organized on September 2, 1890, and subsequently the first examination was made. Ten of eleven candidates passed successfully. Afterward the repeal of the charter of the Medical and Surgical Eclectic College, in Jersey City, was received. In January, 1891, the Board licensed six candidates, and in April last, 25 out of 32 applicants passed. In July, seven out of 15 candidates passed. Up to date 101 candidates have been examined, and 82 were licensed to practise in New Jersey and three in preliminary branches.

**A PRIZE FOR AN ESSAY ON CENTRAL AFRICA.**—The King of the Belgians has offered a prize of twenty-five thousand francs for an essay, embodying the following subjects: The meteorological, hydrological and geological conditions of the districts of equatorial Africa from a sanitary point of view. The principles of hygiene necessary in these districts, with facts showing the best mode of living, forms of diet, and occupation, and the most expedient methods of clothing. The symptomatology, etiology, and pathology of the diseases common to these districts and the principles both of prophylactic and therapeutic treatment thereof, and suggestions to be followed in the choice and dose of drugs as well as in the establishment of hospitals and sanatoria. The competitors for this prize are reminded that in their scientific researches, as in their practical conclusions, they will have to make them apply to Europeans in the various localities of the Congo basin. The competition is open to all. The works of those competing must be transmitted to the Minister of the Interior and Public Instruction at Brussels, before the 1st of January, 1897.

**VIRCHOW'S OBSERVATIONS ON OLD ATHENIAN SKULLS.**—At a recent sitting of the Royal Academy of Science in Berlin, says the *Lancet*, Professor Virchow made interesting communications regarding his measurements of old Athenian skulls dug out by the

late Dr. Schliemann, from his own grounds in Athens. He found eleven graves there, ten of which, judging by their contents, were of the fourth, and one of the sixth century before Christ. All the graves contained human bones, but only four skulls could be taken out in a tolerably unimpaired condition, and these Virchow has measured. All four must have belonged to adults, probably of advanced age. The most remarkable thing about them is the smallness of their capacity. Virchow made a similar observation in 1871 on two skulls dug out in Piræus Street in Athens. One, which belonged to an old woman named Glykera, was of the Macedonian time; in the other grave, that of a powerful man, numerous clay vessels of the most ancient style were found. On that occasion also, Virchow remarked that the small capacity of those skulls was surprising, being so much below the average of other civilized peoples that one was inclined to suppose them to have belonged to members of a savage race. This singular fact should make one pause before accepting capacity of skull as a measure of the civilization of a race, as some anthropologists have done.

## NEW ENGLAND.

**THE ANNUAL REPORT OF THE MASSACHUSETTS STATE BOARD OF HEALTH**, for the year 1890 has recently appeared. The State was unusually free from severe outbreaks of contagious disease. The only noteworthy epidemic was that of influenza, which began in December, 1889, and ended in February, 1890. The total number of cases of small-pox which were reported to the Board during the year was six, and only one was fatal. Several cases of typhoid fever occurred in Newton in the fall, in a limited locality. The Board renews its recommendations, that the present law allowing a town to impose the duties of the local Board of Health upon the selectmen should be made permissive only in the smaller towns. It is also recommended that the weekly returns of mortality which are now sent to the State Board by the local Boards of Health be required by legal enactment, as applied to all cities and large towns. It recommends the continuance of experiments upon intermittent filtration of surface waters and of sewage; the continuance of the work already commenced upon wells used by the public; and the investigation of some of the spring waters that are sold in many of the cities. For these purposes, and to make the necessary investigations in order to advise towns, cities, corporations and individuals in regard to the best method of assuring the purity of intended or existing water-supplies, and the best method of disposing of sewage, and to carry out the other provisions of the statute, the Board estimates that the sum of \$27,000 will be required.

## NEW YORK.

**HOSPITAL SATURDAY AND SUNDAY ASSOCIATION.**—On October 19th the first meeting this season of the Hospital Saturday and Sunday Association was held, and the preliminary arrangements made for the annual collection in December.

ST. LUKE'S HOSPITAL. — The annual meeting of the Society of St. Luke's Hospital was held on October 19th, when the usual reports were read. The chief business coming before the session was the subject of the proposed removal of the hospital from its present site at Fifth Avenue and 55th Street, and the matter was referred to a special committee for consideration. The demands upon the resources of the institution have become so great that more ample accommodations are required.

### Miscellany.

#### VIRCHOW'S SEVENTIETH BIRTHDAY.

VIRCHOW'S seventieth birthday, on October 13th, was celebrated with much pomp and circumstance. According to the *British Medical Journal*, so many congratulatory deputations had been announced that the professor's house did not afford room for all, and the large banqueting hall of the Kaiserhof was therefore chosen for their reception. The first deputation to offer their congratulations was one from the Ministry of Public Instruction, headed by Dr. Bartsch, one of the chief officials of the Ministry. The next deputation consisted of the professors of the medical faculty, headed by the Dean, Professor August Hirsch. This deputation was followed by one from the Academy of Science, headed by Professor von Helmholtz. The deputation bearing an address from the Municipality of Berlin, presenting Professor Virchow with the freedom of the city, was headed by Dr. von Forckenbeck, the burgomaster, who referred in grateful terms to what Virchow had done to improve the health of the city. The address and the accompanying medal, sent by the scientific bodies of Great Britain, were presented by Dr. Semon and Mr. Horsley. Congratulatory addresses were also presented by the medical faculties of Amsterdam, Pavia, Kazan, Warsaw, Brussels, Stockholm, Moscow, St. Petersburg, Berne, Tokio, Upsala, Tomsk, and other places. The military surgeons, represented by Surgeon-General von Coler, and the naval surgeons, represented by Dr. Wenzel, also tendered their congratulations. After an interval of rest, Professor Waldeyer presented the gold medal, which has been subscribed for by Virchow's admirers, in and out of Germany. A silver replica was presented to his wife, and bronze copies to each member of the family and to the scientific bodies which had contributed towards it.

After the ceremony in the Kaiserhof Hotel, a second meeting was held in the large hall of the Pathological Institute. Here an almost endless procession of learned bodies and other corporations, presenting gifts and addresses, defiled before Professor Virchow. The Berlin Medical Society, of which Professor Virchow is president, presented him with his portrait, painted by Professor Lenbach, the presentation being made by Professor von Bergmann. Next came deputations from the Berlin Society of Anthropology and Ethnology, the students of the University, the physicians, the public hospitals, the medical journals, and various other bodies. Dr. Adolph Meyer presented a plant recently discovered by Baron Muller, of Melbourne, in the heights of the tropical mountains of

Australia, which the discoverer had named the "Virchow plant."

The proceedings, which had been commenced at 10 A. M., came to an end at 4.30 P. M. In the evening a *commemorative*, or reunion, of the friends of Professor Virchow, was held in Kroll's Theatre, at which speeches were delivered by Herr Eugen Richter, leader of the Radical party, and others.

#### COMPULSORY MEDICAL EXAMINATIONS.

THE last volume of United States reports contains an opinion of the United States Supreme Court on the question of the right of a court to compel a plaintiff in a suit for damages to submit to a personal examination, in order that his physical condition may be determined.

The question arose in an action brought by a woman against the Union Pacific Railway Company for injuries to her head and spine, caused by the falling of a berth in a sleeping car in which she was travelling. A few days before the trial the counsel for the company moved the Court for an order requiring her to submit to a medical examination in the presence of her own physician and attorneys, if she desired their presence. The Court refused to grant the order, on the ground that it had no legal right to do so. An appeal was taken by the company to the United States Supreme Court. This tribunal sustains the ruling of the lower court. In the opinion of the Supreme Court Justice Gray says:

"No right is held more sacred or is more carefully guarded by the common law than the right of every individual to the possession and control of his own person, free from all restraint or interference of others, unless by clear and unquestionable authority of law. As well said by Judge Cooley: 'The right to one's person may be said to be a right of complete immunity—to be let alone.'"

"The inviolability of the person is as much invaded by a compulsory stripping and exposure as by a blow. To compel any one, and especially a woman, to lay bare the body or to submit it to the touch of a stranger without lawful authority is an indignity, an assault and a trespass, and no order or process commanding such an exposure or submission was ever known to the common law in the administration of justice between individuals, except in a very small number of cases based upon special reasons and upon ancient practice."

Within a few years past the courts in several of the Western and Southern States, following the lead of the Supreme Court of Iowa in a case decided in 1877, have granted orders for the medical examination of persons. Referring to these cases, Justice Gray says: "Upon mature advisement we retain our original opinion that such an order has no warrant of law."

#### THERAPEUTIC NOTES.

A PROLONGED CONDITION OF ACUTE COCAINE POISONING. — Hallopeau<sup>1</sup> describes a condition following acute cocaine intoxication, in which the usual symptoms persist, sometimes for weeks. Several cases are mentioned, and the following conclusions drawn: A single injection of hydrochlorate of cocaine may give rise, not only to accidents, severe and alarming at the time, but also to serious prolonged disturbances. These disturbances are similar to those observed in acute poisoning, especially characteristic symptoms being a persistent headache, with malaise,

<sup>1</sup> Bul. Gén. de Thérap., June 15th.

insomnia, numbness of the extremities, vertigo and prostration combined with cerebral excitement, shown by talkativeness and agitation. This result may be produced by small doses of the drug, and may last several months. It is especially liable to occur in patients of a nervous and excitable disposition, and in intellectual and educated persons.

**CHLOROFORM IN THE TREATMENT OF TUBERCULOSIS.**—At the Congress of Tuberculosis recently held in Paris, M. Desprez,<sup>2</sup> spoke strongly in favor of chloroform as a remedy possessing "truly marvellous antibacillary properties." He has given from one to two grammes of chloroform (by the mouth) daily to a patient for two months without any bad effect; on the contrary, remarkable improvement took place under the treatment. M. Desprez says that washing out tuberculous abscesses with chloroform water yields very satisfactory results.

## Correspondence.

### PLAIN TALKS ON MEDICAL ELECTRICITY AND BATTERIES.

WAYNE, DELAWARE CO., PA., October 19, 1891.

MR. EDITOR:—I have only just now seen your critic's review of "Plain Talks on Medical Electricity and Batteries" (Vol. CXXV, p. 41). Of his estimate of the value or merit of my little book it does not become me to speak.

His remarks upon the current of the coarse wire coil and of the fine wire coil of the Faradic battery are, I think, incorrect.

I wrote, on page 60: "I, some time ago, made the assertion that I quite agreed with Tripin, Apostoli and others in regarding the current of the 'primary' or thick wire as differing in its effects from that produced by the 'secondary' or fine wire." These facts of clinical difference are accepted by almost every competent authority in this country and in France, and can be demonstrated by tapping a long wire—say from one-half to one mile in length—at various distances, and then testing it. The feel of the current is quite different as different lengths are tapped, and is entirely different from the current generated by the coarse wire. Dr. Goelet's thoughtful paper, read at the first meeting of the American Electro-Therapeutic Association, is devoted to this question, and will bear reading. Your critic is right in his estimate of my knowledge of physics. I am a student, and shall possibly remain so until I put by my books forever. But, though he himself may be distinguished as a physicist, he will pardon me for questioning his acumen as an electrical therapist. I may also be wrong in my belief that a profound knowledge of physics is not necessary to a recognition of the differences in the feel of currents. I do it with diffidence, but will your critic allow me to offer the least suggestion possible. Will he test this himself, and also will he adopt the method of Mons. d'Arsonval, and obtain for himself the results of the "characteristic" curve, together with the muscular reaction. These can be traced on the same revolving cylinder, the one above the other. I hope that he will then be brought into the fold, for he certainly has companions in his present homestead. Yours truly,

HORATIO R. BIGELOW, M.D.

[We regret that the author of the above letter should have misunderstood our position, by overlooking the "qualitative" in the review of his book. We will admit freely that a short coil of coarse wire will give a current differing in strength from a long coil of fine wire, owing to the difference in resistance in the coils. To regard the

difference as a difference of quality, or to argue that the size of the wire is an essential factor, is another matter. A Grenet cell will give a current of a different strength from that of a Leclanche, but not of a different quality, and the sole distinction that can be made in practice must be as to the number of cells employed to obtain a given electromotive force. The author will find the reviewer's point sustained by von Ziemssen, Edelmann, and in the excellent little work of Wellington Adams, who may safely be regarded as "competent authorities."—Ed.]

### METEOROLOGICAL RECORD.

For the week ending October 11, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 2,535; under five years of age 4,116; principal infectious diseases (small-pox, measles, diphtheria and croup,

diarrhoeal diseases, whooping-cough, erysipelas and fevers)—, consumption 269, acute lung diseases 183, diarrhoeal diseases 289, diphtheria and croup 110, typhoid fever 94, scarlet fever 31, cerebro-spinal meningitis 19, whooping-cough 19, malarial fever 10, measles 8, erysipelas 7, puerperal fever 2.

From scarlet fever New York 11, Chicago 9, Pittsburgh 5, Brooklyn 4, Cincinnati 2. From cerebro-spinal meningitis New York 5, Chicago, Brooklyn and Washington 3 each, Boston, Worcester, Fall River, Lynn and Taunton 1 each. From whooping-cough New York 7, Chicago and Pittsburgh 3 each, Brooklyn, Washington, Lowell, Cambridge and New Bedford, 1 each. From measles New York 4, Brooklyn 2, Cincinnati and Fall River 1 each. From malarial fever New York 6, Brooklyn 3, Nashville 1. From erysipelas New York and Chicago 3 each, Pittsburgh 1.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,405,108, for the week ending October 31, the death-rate was 18.4. Deaths reported 3,315: acute diseases of the respiratory organs (London) 171, diarrhoea 308, whooping-cough 53, fever 45, diphtheria 39, scarlet fever 31, measles 26.

The death-rates ranged from 12.4 in Portsmouth to 32.4 in Preston, Birmingham 19.4, Bolton 17.6, Hull 24.9, Leeds 16.0, Leicester 19.0, Liverpool 20.7, London 15.7, Manchester 22.8, Newcastle-on-Tyne 25.3, Nottingham 16.7, Sheffield 21.8, Sunderland 24.4.

In Edinburgh 16.7, Glasgow 17.4, Dublin 26.6.

#### OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 17, 1891, TO OCTOBER 23, 1891.

MAJOR RICHARD S. VICKERY, surgeon, U. S. A., is relieved from duty at the Army and Navy General Hospital, Hot Springs, Ark., and ordered to duty at Fort Monroe, Va.

MAJOR CURTIS E. MCNN, surgeon, U. S. A., upon being relieved from duty at Fort Monroe, Va., is ordered to duty at Mount Vernon Barracks, Ala.

MAJOR PETER J. A. CLEARY, surgeon, U. S. A., upon being relieved from duty at Mount Vernon Barracks, Ala., is ordered to duty at Fort McPherson, Ga.

MAJOR JOHN C. G. HAPPESETT, surgeon, U. S. A., upon being relieved from duty at Fort McPherson, Ga., is ordered for duty at Fort Custer, Mont.

CAPTAIN EDWIN F. GARDNER, assistant surgeon, U. S. A., will proceed from Fort Porter, N. Y., to New York City, N. Y., for temporary duty as attending surgeon and examiner of recruits in that city.

MAJOR WILLIAM E. WATERS, surgeon, U. S. A., upon being relieved from duty at Fort Custer, Mont., is ordered for duty at Columbus Barracks, O.

FIRST LIEUTENANT NATHAN S. JARVIS, assistant surgeon, is relieved from duty at Fort Bayard, N. Mex., and ordered for duty at San Carlos, Ariz.

CAPTAIN RICHARD W. JOHNSON, assistant surgeon, upon being relieved from duty at San Carlos, Ariz., is ordered for duty at Fort Bayard, N. Mex.

FIRST LIEUTENANT BENJAMIN BROOKE, assistant surgeon, is relieved from duty at Fort Riley, Kan., and ordered for duty at Fort Leavenworth, Kan.

FIRST LIEUTENANT FRANK R. KEEFER, assistant surgeon, upon being relieved from duty at Fort Leavenworth, Kan., is ordered for duty at Fort Riley, Kan.

By direction of the President, MAJOR PASSMORE MIDDLETON, surgeon, U. S. A., will report in person to COLONEL MELVILLE A. COCHRAN, Sixth Infantry, President of the Army Retiring Board at Newport Barracks, Ky., for examination by the Board.

Leave of absence for one month is granted CAPTAIN DANIEL M. APPEL, assistant surgeon, U. S. A., to take effect about 6th proximo.

CAPTAIN CHARLES M. GANDY, assistant surgeon, U. S. A., granted leave of absence for fifteen days, to take effect on final adjournment of Army Medical Board, now in session in New York City, N. Y.

By direction of the President, CAPTAIN ARTHUR W. TAYLOR, assistant surgeon, U. S. A., will report in person to COLONEL JOHN MINOR MALL, Second Artillery, President of the Army Retiring Board at Fort Adams, R. I., for examination by the Board.

#### SOCIETY NOTICES.

SUFFOLK DISTRICT MEDICAL SOCIETY. — There will be a stated meeting at 19 Boylston Place, on Saturday, October 31, 1891, at 8 P. M.

Papers. Dr. E. M. Buckingham, "Some Uses of the Stomach Tube." Dr. W. M. Conant, "Alexander-Adams Operation."

The paper will be discussed by Drs. Elliot, Harrington and Johnson.

Incidental business: Choice of a committee of five to prepare a list of candidates for officers of the Society.

Supper after the meeting. JAMES J. MINOT, Secretary.

NORFOLK DISTRICT MEDICAL SOCIETY. — The Censors have adjourned till November 3d, 7 P. M. The examination of candidates will take place November 3d, at the office of Dr. J. C. D. Pigeon, 130 Warren Street, Roxbury. The written examination will begin at 7 P. M., the oral at 8 P. M.

Candidates are requested to be prompt, and to bring their medical diplomas, and fee of five dollars.

J. C. D. PIGEON, M.D., Secretary.

BOSTON SOCIETY FOR MEDICAL OBSERVATION. — A regular meeting will be held at 19 Boylston Place, on November 2, 1891, at 8 o'clock.

Drs. H. F. Vickery and G. L. Walton will read a joint paper entitled, "A Contribution to the Study of Chorea, with Especial Reference to its Connection with Heart Disease and Rheumatism." Discussion by Drs. S. G. Webber, C. F. Folsom, F. C. Shattuck, Morton Prince, P. C. Knapp, W. N. Bullard and others.

JOHN C. MUNRO, M.D., Secretary.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY. — There will be a meeting of this Section at 19 Boylston Place, on Wednesday evening, November 4th, at 8 o'clock.

Dr. W. M. Conant will present a Case showing Satisfactory Results of Tendon and Nerve Suture after Injury. Dr. J. C. Munro will show a Case of Gastrostomy for Malignant Disease of the Esophagus. Dr. S. J. Mixer will report Two Cases of Appendicitis, the one complicated by uterine fibroid, and the other occurring during pregnancy. Drs. W. H. Prescott and Joel E. Goldthwait will report results obtained in 531 Cases of Intubation and Tracheotomy.

GEORGE H. MONKS, M.D., Secretary.

#### RECENT DEATHS.

EDWARD RUSSELL, M.D., died in Wollaston, Mass., October 23d, aged fifty. He graduated from the Harvard Medical School in 1862, and immediately enlisted as assistant surgeon, and served in the Twenty-sixth Massachusetts Infantry and Fourth Massachusetts Cavalry until the close of the war. He had not practised medicine for several years.

E. A. OSBORNE, M.D., of Newark, N. J., died October 24th, aged sixty-eight.

M. C. WEST, M.D., of Rome, N. Y., died October 20th, aged fifty-seven.

DR. JACOB POLAK died in Vienna, early in October, aged seventy-one. He was for some time court physician to the Shah of Persia, and the author of several medical works written in Persian, and of a standard work on the flora, geology and archaeology of Persia.

DR. CARL WEDL, Professor of Histology in the University of Vienna, died September 23d, aged seventy-six. He had been Professor since 1872, and was Rector of the University in 1883. He has contributed largely to medical literature.

#### THE UNITED STATES MEDICAL PRACTITIONERS' PROTECTIVE ALLIANCE.

The transactions of the first annual meeting of the United States Medical Practitioners' Protective Alliance have been published and are now ready for distribution to the profession. The volume contains the addresses in full delivered at the Baltimore meeting, together with the Constitution and By-Laws and other information. A copy will be mailed to any physician interested who will send stamp to the Secretary, Dr. J. F. Davidson, Glendora, N. J.

#### BOOKS AND PAMPHLETS RECEIVED.

Tumors of the Naso-Pharynx, Pharynx, Larynx and Esophagus. By W. Cheatham, M.D., Louisville, Ky. New York: D. Appleton & Co. Reprint. 1891.

Weight of the Brain in the Feeble-Minded. By A. W. Willmarth, M.D., Assistant Superintendent Pennsylvania Institute for Feeble-Minded Children. Reprint. 1891.

Essentials of Bacteriology, being a Concise and Systematic Introduction to the Study of Micro-Organisms. By M. V. Ball, M.D. Saunders's Question Compend No. 20. Philadelphia: W. B. Saunders. 1891.

Hand-book of Materia Medica, Pharmacy and Therapeutics. By Samuel O. L. Potter, A.M., M.D., M.R.C.P., Professor of the Theory and Practice of Medicine in the Cooper Medical College of San Francisco. Third edition. Philadelphia: P. Blakiston, Son & Co. 1891.

## Original Articles.

RELATIONS BETWEEN ARTERIAL DISEASE AND VISCERAL CHANGES.<sup>1</sup>

BY GEORGE L. FEARODY, M.D., OF NEW YORK.

(Concluded from No. 18, page 462.)

OF ninety cases of arterio-sclerosis examined by Raelhmann, forty-four showed lesions in the fundus of the eye. The same writer elsewhere<sup>21</sup> records a case of sudden total blindness in a puerperal woman after severe bleeding whose death occurred eight weeks later from a second uterine hemorrhage. Autopsy showed the cause of the blindness to be a condition of arterio-sclerosis with local narrowing of lumen in many places and consecutive retinal oedema.

Much of Raelhmann's work is confirmed by Goldzieher<sup>22</sup> in a recent paper.

These observations have more recently been confirmed and added to by a French writer.<sup>23</sup> He has seen hemorrhages in retina, in choroid, in optic nerve and its enveloping membranes, as well as miliary aneurisms — besides the arterial changes just mentioned. These are regarded as important diagnostic signs of the initial stage of arterio-sclerosis. Inasmuch as liability to aneurism and laceration of arteries is greatest at this time, it would seem logical to warn patients who manifested these symptoms from exposing themselves to exciting causes which are known temporarily to increase arterial tension. It is calculated that the critical period is about the fortieth year as we have seen, and that if, with these early signs of arterial change, men will lead circumspect lives for a few years at this time they may escape the danger of arterio-sclerotic aneurism until the liability is passed, or until the compensatory sclerosis has taken place.

There seems to be experimental proof of much of this. In dogs arterio-sclerosis rarely occurs spontaneously. If the aortic valve is lacerated, the sphygmograph at once shows in the femoral artery all the usual indications of aortic insufficiency. In the next few days no changes are observable in the arterial system. A few days later tortuosity and pulsation of the retinal arteries become visible, and at this time examination of pieces of arterial trunks removed from the body shows that they have become defective in point of elasticity and that they can be dilated more easily than normal arteries. After the lapse of two or three years, the tortuosity of the retinal arteries persists and a diffuse arterio-sclerosis can be distinctly made out by microscopic examination.

The use of the sphygmograph and the importance of an accentuated second aortic sound in diagnosing the increased arterial tension which is often characteristic of the early stages of these changes are both well recognized.

The relation of the sclerotic process to the formation of aneurism is thus conservative, although the antecedent stage of weakness of the media would seem to be a predisposing cause of that grave disease.

We have seen that arterio-sclerosis is a common cause of left ventricular hypertrophy; and yet it is a common experience for every pathological anatomist

to find a small atrophic, pigmented heart when this arterial lesion is combined with aneurism.

This has recently been explained by Högerstedt<sup>24</sup> after the narration of such a case. The way in which arterio-sclerosis causes hypertrophy is by overtaxing the muscular force of the heart by increasing the resistance to be overcome; this occurs in consequence of a diminution of the elasticity of the arterial system. If now an aneurism exist early in the process (and it is not likely to occur late) this lack of elasticity is in part thus compensated and the aneurism aids somewhat in the propulsion of the blood through the diseased arteries. The inference is that the aneurism acts to replace the partially lost elasticity of the arteries, much in the same way that the rubber bulb contributes by its elasticity to the generation of a continuous current in the ordinary hand-atomizer.

If the vascular lesion be once well pronounced it becomes capable of causing grave secondary changes in the region supplied by the affected vessels, as has been already stated.

The combination of a syphilitic eudarteritis with a periarteritis has often been the direct cause of cerebral softening; and in other cases has caused a thrombus to form at its site with the same result so far as the nutrition of the brain is concerned. Cases of this kind have repeatedly come under my observation and been followed to the post-mortem table.

Softening of the brain from diffused arterio-sclerosis has often occurred without the causative influence of syphilis. Such a cause was reported by Ball and Seguin<sup>25</sup> several years ago.

It has occurred very early in life as a lesion of syphilis. In a syphilitic child of twenty months it proved fatal after characteristic disturbances of cerebral function. No autopsy was permitted in this case which is published by Seibert,<sup>26</sup> but the diagnosis seems to have been carefully made.

Leudet<sup>27</sup> records an interesting case of recovery from what he considers to have been syphilitic arteritis. His patient was a man, fifty-three years old. He had the usual "head symptoms," with which we are all familiar, syphilitic infection having occurred four years previously. But in addition to these symptoms he manifested others of unusual occurrence, that is, he suffered from lancinating pains in the scalp in the neighborhood of branches of the temporal arteries. These vessels gradually became stiff, hard and swollen. All symptoms gradually disappeared after four months of specific treatment.

Here the lesion occurred in superficial arteries coincidently with its occurrence in those of the brain; and its cure was brought about in both sets of vessels by ordinary specific treatment.

It seems occasionally to cause death in early life by cerebral hemorrhage. It is probable that aneurism-formation is the immediate cause of the rupture of arteries, in young subjects as in old, when it occurs early in arterio-sclerosis.

Some years ago a boy, nineteen years of age, died of cerebral hemorrhage in the New York Hospital in whose arteries this lesion was very distinct. (Fig. 1.) I have the pleasure of showing you a few sections of one of his internal carotid arteries in which the sclero-

tic process is well seen. W. J. F., was a canvasser by occupation. He was said to have been in good health prior to this illness. Unfortunately his history is meagre. He was known to be well at 1.30 A. M. on

FIG. 1. Internal carotid artery of boy nineteen years of age, who died of cerebral hemorrhage. It shows lesion of arterio-sclerosis. Numerous other arteries showed same lesion.

December 4, 1884. Two hours later he was found comatose and was brought immediately into the hospital. Fifty minutes after he was found in this condition he died, having remained absolutely comatose all the time.

cases of congenitally small aorta, like this one, there seems to be a tendency towards the development of degenerative changes in the intima, such as sclerosis and atheroma; and occasionally also fatty changes in the media and myocardium. He also speaks of hypertrophy of the left ventricle as occurring in this condition.

I regret that at that time I was not specially interested in this subject, hence my investigation of this case, both clinically and anatomically, must appear to you very unsatisfactory.

It would be easy to adduce many cases of death from this disease in the cerebral vessels, occurring in middle life; but it would, perhaps, not be profitable to do so. It is sufficient to say that it is common; that it is often of syphilitic origin; that it is then usually accompanied by definite symptoms, of which pain is a marked one; that it is likely to be associated with periarteritis; that it disturbs brain function by depriving specific areas of their blood-supply; that it may do this with or without an accompanying process

FIG. 2. Longitudinal section of left vertebral artery, showing arterio-sclerosis, with syphilitic periarteritis. The other arteries at base of brain showed similar lesion, and there was thrombosis of the basilar, which caused death. Patient was forty years of age, and had suffered from intermittent severe headache for a year. He died untreated.

a, Thickened intima. b, Lamina elastica. c, Media. d, Adventitia. e, Small artery of adventitia showing same lesion.

The autopsy which I made several hours later, showed very extensive cerebral hemorrhage with great laceration of brain; and besides this it showed arterio-sclerosis very generally throughout the body. I have records of the presence of this lesion in both internal carotids, one common carotid, both renal arteries and the small arteries in the substance of both kidneys. The aorta was very small, measuring in diameter at the beginning of the transverse portion of the arch 16 cm.; at its bifurcation, 1 cm.

There was distinct hypertrophy of the left ventricle, and the kidneys were atrophied and showed by microscopic examination the lesions of chronic diffuse nephritis.

Virchow<sup>28</sup> has called attention to the fact that in

of thrombosis; that it is, when due to syphilis, very amenable to treatment, if the treatment be sufficiently early and sufficiently energetic; that if it be not properly treated it is likely to lead to death by cerebral softening. (Fig. 2.)

All of this is commonplace. Less so is the question as to whether death can be caused by this lesion, preceded by symptoms of disturbance of brain-function, such as hemiplegia, aphasia, etc., *without lesion* of the brain. I believe that it can, that it has occurred in my own practice. The following case<sup>29</sup> published elsewhere some years ago, seems to illustrate this possibility:

J. M., aged fifty-six, a native of Ireland, widower, a tailor by occupation, was admitted to my service in the New York Hospital, April 22, 1886. He gave

<sup>28</sup> Ueber Chlorose u. die damit Zusammenhängenden Anomalien im Gefäßapparate. n. w. v. Berlin. A. Hirschwald, 1872; also Schmidt's Jahrb., 1872, vol. 156, p. 309.

<sup>29</sup> New York Medical Record, 1886, p. 65.

the following history: his mother was rheumatic; of his father he knew but little. He said that he (the patient) had had rheumatism in his hips for six years. He denied malarial history. He had a soft chancre years ago, and suppurating bubo, but he denied symptoms of syphilis. He had partaken immoderately of spirits for the past twelve years. During the entire past winter he had suffered from a continuous headache, and from ringing in the ears. He had not been dizzy. About ten days ago he suddenly fell to the floor, and was unable to move either of his right extremities, and was unable to talk. He did not lose consciousness. In half an hour he was able to talk, and power had returned in great measure to his leg, but less completely to his arm. Recovery, however, was ultimately complete. Four or five times since then he has had slighter attacks of a similar character, when he could not speak or move, but recovered always in a few minutes. There was never any loss of consciousness. He never had an attack before ten days ago. His appetite was fair, his bowels regular, his temperature 100.6°, respiration 24, and pulse 82. On his admission to the hospital at 11 A. M., he was senile; his superficial arteries were stiffened and tortuous. He was poorly nourished; there was no oedema. There was incomplete right facial paralysis. The tongue, on being protruded, deviated to the right. There was well-marked right hemiparesis; there was no disturbance of sensation.

There was lateral curvature of the spine; the chest was barrel-shaped; the heart-sounds were normal.

His urine gave the following results on examination: Reddish-yellow, acid, 1,024, no albumen, negative microscopically.

*Treatment.*—Iodide of potassium, twenty grains every three hours.

April 23d, at 3 A. M., he had a seizure, characterized by loud, gasping, stertorous breathing, and complete inability to speak or protrude his tongue. His pupils were normal. He could move both arms and legs, but there was marked diminution in the power of both of his right extremities. Consciousness was complete. In about half an hour he recovered from this attack, was able to speak perfectly, and told accurately all that had happened. He could protrude his tongue readily. It deviated somewhat to the right. His temperature and pulse were normal; his respiration somewhat accelerated. The iodide of potassium was increased to thirty grains at a dose. He felt well, and was allowed solid food at his own request. In the absence of the attendant he tried to get into bed from the night stool this morning, but fell and was unable to get up without assistance. At 5.30 P. M., he had an attack similar to the previous one. It lasted forty minutes. Recovery from it was slower and less complete. He could soon protrude his tongue, but with difficulty. He could talk so as to be understood, but talking was difficult, and his speech was indistinct.

April 24th. During the early part of the night he again got out of bed and fell, and was quite restless. He said that after both attacks his head ached very severely, and he was unable to eat. Very early this morning he had a similar attack, but much more severe than any of the previous ones. At 4.30 A. M., he was still suffering from it, was conscious, but now was entirely unable to move the right side. At 9 A. M., he was unconscious, in a profuse perspiration,

and breathing with marked stertor. His temperature was 104° F., respirations 52, pulse 129. He continued in this state, rapidly growing weaker, till 1.45 P. M., when he died. The temperature after death was 105.8° F.

The autopsy was made about an hour after death. The weather was warm, and therefore, to prevent the occurrence of post-mortem changes, the body was taken directly from the ward to the autopsy-room. It was fairly nourished. Rigor mortis was absent. There was no oedema. The organs generally were normal. The cortices of the kidneys was a trifle thin, but the surfaces were smooth, and the markings distinct. There was slight hypertrophy of the left cardiac ventricle. There was a mass of grayish-yellow material in the liver, measuring two by three centimetres. It contained caseous material, and proved on examination to be surrounded by a layer of connective tissue, and to be an old gumma.

With the exception of the brain, now to be described, the other organs were substantially normal.

The arteries in the circle of Willis showed several small, insignificant patches of atheroma. In most of them, notably the basilar and left middle cerebral, there was a well-marked growth of connective tissue in the wall of the intima. The calibre of the vessels was thus distinctly encroached upon, but by no means completely obliterated. In many of these regions was found the small-celled growth of periarteritis as well. There was no alteration in the color or consistency of any part of the brain, and no other change was found. A microscopic examination of the affected arteries showed the lesion to be arterio sclerosis, which involved to a varying degree almost the entire circumference of the vessel. The lumen was thus not obliterated, but very materially encroached upon.

The possibility of the occurrence of death under such circumstances with brain-symptoms, but without brain-lesion, is alluded to by Delafield and Prudden;<sup>80</sup> but I have not found any recorded cases. The explanation of the cause of death here is not entirely clear. It seemed to me that there might perhaps have been a spasmodic contraction of the muscular coat of the middle cerebral artery, or of several of its branches, which, in addition to the encroachment upon its lumen produced by the new growth, was sufficient to cut off blood-supply to the parts to which it is distributed; that this had occurred several times, each time causing temporary ischemia of important brain centres; and that in the final attack it had lasted long enough to produce death, but that it was not complete enough, or of long enough duration, to cause softening.

That similar arterial spasm takes place in the retina<sup>81</sup> and can be seen with the ophthalmoscope, there seems to be abundant evidence; that it occurs in the coronary arteries seems extremely likely, from the occurrence of sudden death from cessation of heart-action without embolic or other permanent closure of a sclerosed coronary artery. I have myself diligently sought to find other cause of sudden death in a subject of angina pectoris, whose heart muscle was not degenerate, and believe that arterial spasm alone will account for it under these circumstances.

The effect of this disease occurring in the coronary arteries has been very carefully studied, and many

<sup>80</sup> Handbook of Pathology, Anatomy and History, New York, 3d edition, 1889, p. 290.

<sup>81</sup> E. G. Loring: New York Medical Record, 1886, pp. 79 and 80.

contributions have been made to the literature of this part of the subject. Independently of the serious effects produced in this way, there seems to be good ground to believe that valve-lesions, especially of the aortic valve,<sup>82</sup> are often caused by changes in the small arteries which supply them.

That angina pectoris should be produced by this lesion in the coronary arteries needs only to be mentioned. In passing, it may be proper to say, however, that this is not the only cause of that serious and painful disease. That arterial spasm, localized and general, seems to be brought about by this lesion, as already remarked, seems again proved by the fact that attacks of angina often are accompanied by differences in radial pulses,<sup>83</sup> by localized areas of anaemia, and by increased arterial tension in general. Sudden transitory blindness is known to occur in one or both eyes in conditions of aortic stenosis, and the explanation offered for it is spasm of the cerebral arteries.<sup>84</sup> It is known that in generalized arterio-sclerosis sudden complete blindness can occur with no lesion of the eye visible with the ophthalmoscope. The most plausible explanation seems to be supposed vascular changes in the occipital lobes.

Fibrous myocarditis is a common lesion following the occurrence of this change in the coronary arteries. It is not long since a sudden death came under my notice in the person of a prominent surgeon from the supposition of thrombosis upon the existence of those two lesions in the structure of the heart. Thrombosis is exceedingly common in consequence of the roughening of the arterial wall which is frequent in advanced conditions of this lesion.

The various consequences of fibrous myocarditis, from the functional disturbances which it causes to the development of cardiac aneurism, need not occupy our time.

Much interesting material upon this subject has been collected by Lüttich, of Hanover, in Schmidt's *Jahrbucher*, vol. cvii, p. 22. The most important paper there quoted is by Leyden.

It is not at all necessary for the muscular structure of the heart to have become degenerate as a consequence of sclerosis in order to account for sudden death occurring from the sudden stoppage of a coronary artery.<sup>85</sup> The heart-muscle may be healthy or even hypertrophied under these circumstances.

In slowly developing conditions of fibrous myocarditis the heart may become very extensively diseased before serious symptoms result, and death may occur only after protracted feebleness and suffering.

Acute thrombotic softening, or hæmorrhagic infarction in the myocardium can occur in consequence of sclerotic thrombosis of a coronary artery. This lesion occurs most frequently in the wall of the left ventricle, and is the commonest cause of rupture of the heart.

When the heart-muscle is degenerate in association with lesion of the coronary arteries, we are apt to find the fibrous change in it to which reference has just been made. Fibrous masses may be diffused through the muscle or there may be only a circumscribed area of such tissue. In this latter case it is usually situated in the left ventricle, near the apex, and is not seldom the origin of a cardiac aneurism.

The symptomatology of fibrous myocarditis is of extreme interest, but would take us a little too far from our subject.

Demange<sup>86</sup> has published four cases of disseminated spinal sclerosis associated with general arterio-sclerosis. In some of these the arterial lesion is most pronounced in the cord. Miliary aneurisms are common, and hæmorrhages into perivascular spaces.

In one case a copious hæmorrhage occurred in cervical cord. A perusal of his cases would lead to the belief that the disease which he describes differs in its symptoms, as it does in its etiology, from the ordinary disseminated sclerosis.

Mendel<sup>87</sup> claims to have found arterio-sclerosis in several small branches of the middle cerebral in a case of progressive paralysis of the insane. He believes that it may be the indirect cause of hydrops of the pericellular spaces, causing congestion of lymphatics, in consequence of its disturbing influence over arterial and venous circulation. He thinks, apparently, that it may be a frequent (possibly essential) lesion in progressive paresis.

Numerous instances are recorded of serious disturbances of nutrition of extremities associated with this lesion of the arteries.

Will<sup>88</sup> narrates a case in which gangrene occurred in both upper extremities, from finger-tips to middle of forearms. The patient was fifty-two years old, not syphilitic, and no other causative influence could be found. This is said to be the third carefully examined case of this kind.

Hutchinson<sup>89</sup> and Klotz<sup>40</sup> ascribe gangrene of lower extremities to this lesion, and record cases in point.

It seems not unlikely that this condition may have more to do with senile gangrene than has been supposed.

D'Ornellas<sup>41</sup> describes a case of gangrene of the fingers in a syphilitic, necessitating amputation. The patient was forty-five years old, and had been infected by syphilis twenty years previously. Pulse was absent in radial, ulnar and palmar arch, as well as in lower third of brachial. The arteries felt like tough cords. Under specific treatment the patient made a good recovery, except so far as the loss of his fingers. He was seen by Fournier, Verneuil, Duplay and others, who concurred in the diagnosis.

Hutchinson<sup>42</sup> describes a case of senile obliteration of temporal arteries in a man eighty years of age, apparently due to sclerosis. The vessels felt like hard cords. While the process was going on, there were much pain and tenderness in them, both of which disappeared when it became complete.

There was no gangrene nor any other symptom than those mentioned.

Thoma's<sup>43</sup> discovery of the presence of pacinian bodies in arteries explains the occurrence of pain as a symptom of arterial disease. He believes that many of the rheumatoid pains, which occur in the chest in people from thirty-five to forty-five years of age, are to be thus explained. Thus, also, he explains the pain

produced by a beginning aneurismal dilatation, before it is large enough to press upon surrounding parts. By their involvement one would explain the acute pain produced by the lodgement of an embolus in a peripheral artery.

## PHLEBO-SCLEROSIS.

Of late years evidence has accumulated which goes to show that a similar lesion exists in the veins. A paper, by Sack<sup>45</sup> is instructive as showing its relation to the lesion in the arteries. It is shown that the two sets of vessels are likely to be simultaneously affected in the same individual, and the lesion in the veins probably does not differ in etiology from the arterio-sclerosis.

According to Sack, phlebo-sclerosis occurs most commonly in the lower extremities, a fact which is also true of the arterial lesion. He ascribes its frequency in this location to the sluggishness of the circulation here and to variations in blood-pressure. Not only in general, from their dependent position, is the circulation less active in the lower extremities than elsewhere, but there are likely to occur local causes of congestion in them, such as ascites, pregnancy, heart disease, etc.

The nodose form does not exist in the veins. When disseminated patches are found in them, it is likely that they represent the beginning of the diffuse form.

Pokrovsky<sup>46</sup> has also published an elaborate paper on phlebo-sclerosis. He claims that there is a nodose form of the affection, and that many consecutive changes and degenerative processes follow and accompany it. Spillmann,<sup>46</sup> of Nancy, has written lately on the same subject. He quotes extensively from a thesis by Henry Thiebaut,<sup>47</sup> who seems to have devoted much time and attention to this subject.

Although numerous writers concur as to its existence and distribution, no one seems yet to have been able to trace to it any grave consequences. Similar lesion has been also found in the capillaries. Here the disturbance of function produced manifests itself by an increased permeability of their walls, in consequence of which oedema of the tissues result.

The process seems to be so widely spread throughout the vascular system as to justify the name angio-sclerosis which several observers have applied to it.

## ON THE ETIOLOGY OF EPILEPSY, WITH SPECIAL REFERENCE TO THE CONNECTION BETWEEN EPILEPSY AND INFANTILE CONVULSIONS.<sup>1</sup>

BY G. L. WALTON, M.D.,

Physician to the Neurological Department of the Massachusetts General Hospital,

AND C. F. CARTER, M.D.,

Assistant Physician to the Neurological Department of the Massachusetts General Hospital.

BEFORE considering the relation between infantile convulsions and epilepsy, it will be well to fix in our minds the true meaning of the various expressions which denote increased muscular action, as even the fundamental matter of definition furnishes confusing inconsistencies in the works of the most recent author-

ities, in which we not infrequently find the terms contraction and contracture, spasm and convulsion, used almost interchangeably.

*Contraction*, or drawing together, implies in itself nothing pathological, but is a general term applied to the shortening of any tissue, though most commonly used regarding muscles; this process may be either physiological or pathological.

*Contracture* is a more or less permanent contraction.

*Spasm* is an involuntary contraction of muscular tissue, and may be tonic or clonic.

*Convulsion* is a generalized spasm, either tonic, clonic, or both, and is likely to be accompanied by loss of consciousness and other manifestations, though not necessarily so.

All these terms are used to describe symptoms, whereas *epilepsy* is an idiopathic disease, that is, "a disease conceived by itself, which is distinguished from eccentric convulsion, from the spasms of poison, from the convulsions that result from organic changes in the cerebro-spinal centres, and from every other form of known and recognized disturbance. It is certainly true, that an irritation of the foot, in the digestive tract, or in the convolutions of the brain, may cause, not only simple convulsions but also epilepsy proper, still, the difference should be recognized. Convulsions imply a condition of increased irritability; in epilepsy this irritability has an existence of its own, depending upon a faulty nourishment which exists after the eccentric irritation has been removed." (Reynolds.)

The distinction so clearly enunciated many years ago seems to have been curiously overlooked by some of the most recent writers, whose efforts at classification lead the reader into numberless contradictions, and retard, rather than advance, our knowledge of the subject.

In illustration we will only quote Hamilton, who, in Wood's "Hand Book," after defining epilepsy as a disease in which sudden losses of consciousness are attended by more or less convulsive muscular action, proceeds to describe a case of defective mental development with malformation of the skull, as an epileptic, and to include under the causes of epilepsy meningeal or osseous thickening, exostoses, vascular dilatation and sclerosis-atrophy or hypertrophy, and the existence of tumors, all varieties of fracture and depression, and subdural cysts, also protracted hemorrhage and metallic poison; the convulsions following sunstroke, however, with curious inconsistency, he regards as hardly true epilepsy. This author even gives the reader to understand (page 706) that the convulsive seizures of general paralysis should be classed under epilepsy, with accompanying dementia. Thus, under the morbid anatomy and pathology of *epilepsy*, he states that "in cases where dementia or other mental troubles are found, and especially in those in which the mental disturbance takes the form of general paresis, we may expect to find a well-diffused cortical sclerosis."

Again, while he states that uræmic and alcoholic convulsions should be differentiated from epilepsy, he includes metallic poison under its etiology — a distinction hard to understand.

In clear-cut contradiction to these confusing statements, Westphal has said, "Not every patient with mental or nervous trouble, who has epileptoid or epileptiform attacks, should be classed as an epileptic."

In epilepsy it may fairly be assumed that an exalted

<sup>47</sup> Gazette de Med, et de Chir., 1890, p. 480.

<sup>48</sup> These do Nancy, 1890.

degree of irritability exists in certain motor centres. Whether those of a special convulsive area in the pons or medulla, as held for example by Küssmaul and Tennen, Brown-Sequard, Schiff and Nothnagel, or in the cerebral cortex, as held by Ferrier, Luciani, Bartholow, Unverricht, Munk, Bubnow, Heidenheim and Horsley,<sup>2</sup> the writers will not at present commit themselves to an opinion. This irritability renders liable a general convulsive discharge on slight provocation, or even, at intervals, spontaneously. It is this underlying condition which constitutes the *disease*, the *convulsion* being only a symptom, nor is the convulsion even an essential symptom—as is evidenced by petit mal—the loss of consciousness being far more constant.

Writers are practically unanimous in ascribing to heredity the chief place in the etiology of epilepsy, mentioning not only the neuroses and allied neurotic temperament, as well as epilepsy proper in the ancestry, but also apoplexy and other organic affections of the central nervous system, which depend in no degree on a neuropathic taint. It is hard to see how the latter can play a very conspicuous part in the causation of epilepsy, in the progeny of the sufferer, however liable they may be to produce convulsions in his own case; and even regarding the neuroses, the investigations of the writers would lead them to the belief that even this connection has been overestimated. Migraine, for example, has been somewhat extensively regarded as analogous to epilepsy, while in point of fact their only similarity lies in a spasmodic recurrence with intervals of freedom. That one can pass into the other, or beget a tendency to the other in the progeny, is a matter of great doubt.

Wilks,<sup>3</sup> dissenting from the prevailing view on this point, states that he has only known of one case where the two affections co-existed, and has never known the one disease to pass or develop into the other. He alludes to the remarkable exemption of epileptics from headache, and dwells on the fact that remedies act far differently on the two, for example, antipyrine and the bromides.

Again, Lamoine<sup>4</sup> in discussing the etiology of epilepsy, is inclined even to deny the inheritance of the disease, and allows a secondary part to hereditary neurotic predisposition.

The discussion of this point may be left to a future investigation, and it is only mentioned here in passing, to show that the long-established views on the simple question of heredity are not universally accepted.

Coming to the question with which we are chiefly concerned in this paper, namely, the connection between infantile convulsions and epilepsy, a study of the authorities shows an almost unanimous expression of opinion that the former predisposes to the latter, a position which the writers consider untenable.

In infancy we have physiologically to do with an irritability analogous, perhaps, to that already mentioned as characteristic of epilepsy, so that convulsions are brought about by sources of irritation either inactive in the adult, or producing a different train of nervous symptoms less explosive in character. This irritability is, however, during the period of early development, physiological in the majority of cases, not pathological, and we should be chary of pronouncing

the resulting convulsions epileptic. This does not, of course, preclude the possibility that we have to do with one of the exceptional cases where convulsions mean epilepsy, beginning in childhood, a question which can only be determined by their continuance and nature. We have no more right to associate with epilepsy infantile convulsions arising upon intestinal or other irritation, through the agency of this physiological irritability, than we have to regard the regurgitation of food at this age as due to a pathological state of the vomiting centre. Indeed, the feverish condition which usually precedes the convulsions of infancy is in marked contrast to the condition preceding a true epileptic attack.

Such a course of reasoning as this will lead us to view the cases, as they present themselves, free from bias, and should prevent our acceptance of isolated cases of coincidence as proofs of an underlying principle, an error into which we are liable to fall if we accept blindly the dictum of tradition.

This subject should not be regarded as one of simply scientific interest, for we are forced in practice to express definite views upon it, and the realization that our answer may remove or deepen, as the case may be, a warrantable anxiety on the part of parents and friends, will lead us to consider carefully all evidence bearing upon the point at issue.

Let us consider, first, the age of commencement of true epilepsy. Statistics will naturally vary somewhat, but our observations agree in a general way with those previously published, at least to the extent of showing that true epilepsy *may begin* in infancy, and become continuous, a fact which will prevent our going to the opposite extreme and assuring the parent that there is *no* liability that the convulsions will continue.

Starr<sup>5</sup> has formulated the following table.

AGE OF ONSET.	
Birth to 5 years	29 cases.
5 to 10 years	22 "
10 to 15 "	30 "
15 to 20 "	16 "
20 to 30 "	30 "
30 to 40 "	9 "
40 to 50 "	8 "
50 to 60 "	3 "
Age unknown	18 "
Total	165

Moreau's tabulation,<sup>6</sup> of 995 cases is as follows:

At birth	87 cases.
Infancy	25 "
2 to 10 years	284 "
10 to 20 "	364 "
20 to 30 "	111 "
30 to 40 "	59 "
40 to 50 "	51 "
50 to 60 "	13 "
60 to 70 "	4 "
Total	995

According to Starr, therefore, 59 per cent. began before the age of 20 and according to Moreau 76 per cent.

Our own tabulation of 133 cases, treated during the last three years at the Massachusetts General Hospital, is given in the next column.

Percentage up to the age of 20=58. A comparison of our percentages with those of Starr shows a marked similarity.

The 133 cases mentioned by the writers, occurred

<sup>1</sup> For theories regarding pathology, with bibliography, see Prize Essay, *Am. J. Hyg.*, F. A. Davis, 1901.

<sup>4</sup> *Mém. de l'Académie de Méd.*, Paris, 1853.

amongst 2,539 cases of all varieties applying for treatment at the Neurological Department of the hospital, making a percentage of  $5\frac{1}{2}$ , a proportion slightly lower than the estimate of Reynolds (about 7 per cent of all cases of nervous diseases), also than that of Putzel (a little over  $6\frac{1}{2}$  per cent).

The lower percentages found by the writers, unless possibly accidental, are probably due to care in limiting the diagnosis.

AGE OF ONSET.		
Birth to 5 years	20 cases.

On reviewing the literature concerning infantile convulsions as a predisposing factor in epilepsy, one finds a prevailing, though not unanimous, affirmative opinion.

Neimeyer says: "It (epilepsy) begins not rarely, in the first years or months of life; one finds, also, sometimes, that patients in whom the disease first declared itself later, suffered already in early childhood from convulsions."

Webber:<sup>7</sup> "Severe and prolonged convulsions in infancy are very frequently followed by epilepsy later in life."

Starr<sup>8</sup> states that "infantile convulsions are the most common of all predisposing causes of this disease."

Nothnagel:<sup>9</sup> "In hereditary epilepsy the attacks are apt to begin before the twentieth year. Such patients suffered from eclampsia often in first dentition and remain apparently healthy until the outbreak of epilepsy."

Althaus:<sup>10</sup> "Where epilepsy is hereditary, the infant is liable to attacks of eclampsia, and true epilepsy is developed about, or at any time previous to puberty."

Among other authors expressing the same opinion, may be mentioned Rosenthal,<sup>11</sup> Hamilton,<sup>12</sup> Bastian,<sup>13</sup> Brown-Séquard,<sup>14</sup> Seguin and Ranney.<sup>15</sup>

A certain degree of dissent from the prevailing view on this point has been already expressed.

Putzel<sup>16</sup> says, for example: "We not infrequently notice that epileptics have suffered from eclamptic attacks during the period of dentition, and some authors believe that frequently recurring eclamptic convulsions may produce an epileptic habit in the brain, and thus give rise to the independent existence of epilepsy. But the eclampsia of childhood is so overwhelmingly more frequent than epilepsy that we are very sceptical

with regard to its efficiency as a cause of the latter affection."

Hammond:<sup>17</sup> "They (infantile convulsions) may pass into epilepsy; but if they do not, I have never been able to find a single instance in my experience in which epilepsy ensuing in adult life has been preceded by the ordinary infantile convulsions." This experience would point to the fact that infantile convulsions once discontinued, no fear need be expressed that epilepsy will ensue later, a view which coincides with our own, though our experience is not identical with that of Dr. Hammond, that no case of infantile convulsions has been found to precede epilepsy, our observations showing, however, no more such cases than can be explained by coincidence, as our tables will show.

Eustace Smith<sup>18</sup> says: "As a rule, single fits, or convulsions occurring without other signs of nervous lesion in a healthy child, are purely reflex, and have no gravity whatever."

Flint:<sup>19</sup> "A paroxysm of convulsions in an infant or child often, with good reason, occasions anxiety lest it may prove the beginning of epilepsy. It is not always practicable to determine the point at once. There is more reason to apprehend epilepsy in proportion as the convulsions are not otherwise to be accounted for. Their non-recurrence affords the only positive proof that they are not epileptic."

From an *a priori* point of view it might be assumed that the children most liable to have convulsions on a given irritation, possessed a greater convulsive tendency than others, and might therefore be expected to offer a somewhat more probable basis than others, for future attacks. When we come to consider, however, the vast and vital step from simple reflex convulsions to true epilepsy, this argument will not weigh very heavily, against facts. It is to these facts, as far as come under our experience, to which your attention is called.

We have carefully analyzed 70 successive cases of pure epilepsy in hospital and private practice with reference to the question of previous infantile convulsions, the opportunity being also taken to find out whether the brothers and sisters have been subject to them. The first point was to discover the relative tendency for the two affections to fall together or separately in the same family. The number could have been made much larger, but care has been taken to exclude cases in which trauma or organic brain disease was likely to have played a part, as well as those in which uncertainty existed regarding the early history. We are almost of necessity restricted in this investigation to those cases whose parents we are able to question, as few persons, well or otherwise, can be depended upon to state whether they themselves or their brothers and sisters had convulsions in infancy. Of these 70 cases, nine commenced in infancy and became continuous; 56 had no history of convulsions in childhood, five only had a history of infantile convulsions followed by a period of immunity.

Of these five cases the history was as follows:

CASE I. Typical epileptic. An infantile convulsion occurred at the age of one year, nothing further appearing until the age of sixteen, when true epilepsy began.

CASE II. Typical epileptic. Had a single convulsion at the age of two. Epilepsy commenced at the age of twelve.

CASE III. Petit mal. Had four infantile convulsions between the ages of one and four. Present trouble began at eleven.

CASE IV. Typical epileptic. Had infantile convulsions. Epilepsy appeared at twenty-seven.

CASE V. Typical epileptic. Had three infantile convulsions in one year. Epilepsy began at fourteen.

Apart from these five cases there were none among the seventy cases investigated, in which infantile convulsions had occurred, to disappear and be replaced by epilepsy, though, as stated, in nine the epilepsy came on in infancy and remained constant. These nine cases alone would show the possibility of epilepsy beginning at an early age, a fact already established, and should put us on our guard against assuring the parent of a child with its first infantile convulsion, that epilepsy is not to be considered at all. Such convulsions having, however, once disappeared, it would seem that we may reassure them with confidence, for the proportion of five in seventy (one in fourteen), is too small to be regarded as any more than a coincidence.

Curiously enough, the investigation of the *other children* (grown-up) in the families of epileptics has shown a much larger proportion of infantile convulsions among them than among the epileptics themselves, a fact which may possibly show an abnormal convulsive tendency in such families, but illustrates in a striking manner the absence of interdependence between the two affections. J. Lewis Smith, in support of the same view, even states that he has been struck by the *immunity* from infantile convulsions among epileptics, though we hardly imagine that the word immunity was meant to be taken too literally.

Various estimates of the percentage of epileptics in a community range around six in one thousand, no estimate being much higher than this. No statistics previously existing as to how many cases of infantile convulsions occur in a community, the writers have collected data on this point with the following result: Out of one thousand children taken consecutively at random from all classes of society, 111 have been found to have a history of infantile convulsions. Now, taking the percentage we find of infantile convulsions among epileptics (one in fourteen), we have the two affections occurring coincidentally once in two thousand individuals. When we consider how many cases, therefore, of infantile convulsions occur in every two thousand individuals by our statistics, (approximately 220,) it is at once evident how rarely the one condition is followed by the other. This would reduce the chances of a given child with infantile convulsions becoming an epileptic later in life, to something like one in 220, certainly hardly sufficient to warrant alarm, even allowing a balance for difference in statistics, for one in 220 is certainly no more than the average chance of ordinary individuals if six in one thousand is the usual rate. It would certainly seem that the proportion of one in fourteen as compared to one in ten, would place us on the safe side in saying that epileptics are at least no more liable than others to have had infantile convulsions, and conversely, that a child suffering from infantile convulsions is no more likely than any other to suffer from epilepsy later in life, after a period of immunity has removed the case from the

class of epileptics beginning in infancy and becoming continuous.<sup>20</sup>

#### CONCLUSIONS.

(1) Epilepsy may begin in infancy and become continuous.

(2) Where infantile convulsions have ceased for a sufficient time to remove the case from the class mentioned under Conclusion I, the child is no more likely to become an epileptic than any other individual.

#### A CASE OF INTESTINAL ANASTOMOSIS, BY MEANS OF SENN'S PLATES, FOR THE RELIEF OF COMPLETE CHRONIC OBSTRUCTION CAUSED BY INVAGINATION AND SLOUGHING OF THE UPPER PART OF THE ILEUM. RECOVERY.<sup>1</sup>

BY JOHN HOMANS, M.D.,

Surgeon to the Massachusetts General Hospital, Boston, Mass.

ABOUT the first of December, 1890, Dr. F. W. Chapin, of Springfield, Mass., wrote me in regard to operating on a case of intestinal obstruction. A day or two later he wrote that consultation had decided that the child was too weak to bear any manipulation. On December 21st, he wrote the accompanying letter:

SPRINGFIELD, MASS., December 21, 1890.

MY DEAR DOCTOR:—The patient, a girl ten years old, about whom I sent you a note the other day is alive and perhaps in as good condition as when I wrote. The history of the case is somewhat peculiar. Last July she was suddenly taken with severe vomiting and symptoms of collapse. A sausage-like swelling appeared in the left iliac region, which could not be felt by the rectum. The vomiting was not fecal nor of fecal odor. I finally concluded that there was impaction, gave a dose of calomel, and she immediately recovered. At times during the summer, however, she would have pain in the bowels, and on one occasion vomited a good deal. In September, or early in October, she was taken down again in about the same way as in July; a dose of calomel was given and partial relief was obtained, but the next day excruciating pain came in the bowels, a tumor appeared lying across the epigastric region, or a little below, and complete obstruction followed. About the first of November she passed a piece of intestine, and was better for a few days, one or two small fecal discharges taking place. Obstruction returned, however; and finally, about three weeks ago, a movement (small and flattened) was obtained by means of calomel. We have not been able to get anything through her since then. She has not vomited much, has taken a little nourishment by the mouth, but has been chiefly fed by the rectum. She is greatly emaciated, and her pulse is small and feeble generally, though sometimes of considerable volume under the influence of morphine, of which she takes about one-eighth of a grain every four to six hours hypodermically. She has always been a rather delicate child, and has had several attacks of bronchitis. I have thought that there may be tubercular trouble of the intestines in addition to the purely mechanical trouble. I had three local physicians see her with me about the time I wrote you, and they all

<sup>1</sup> Read before the Boston Society for Medical Improvement, May 25, 1891.

<sup>20</sup> It may be objected to our statistics, that the parents' word was taken regarding infantile convulsions. This is, however, the ground upon which the statement in the text book has been based, in which epileptics are said to have had infantile convulsions; in fact such statements are the only data upon which we can proceed. These statements may err, it is true, but the errors will tend to counteract each other after all, for whereas some parents may mistake something else for a convulsion, others will overlook or conceal them. We have taken the greatest care to exclude as far as possible convulsions arising from organic disease, and in one family where each of six children is stated to have had convulsions during scarlet fever, the entire family was excluded.

felt confident that the patient was too feeble to endure an operation. We told the parents that there was perhaps a ghost of a chance that an operation would relieve her, but that there was no reasonable chance. They then said that they preferred not to have the operation undertaken. When the movement from the bowels was obtained three weeks ago (small and flattened, as I have said), I felt that, although there was evidently a stricture at the point where the intestine sloughed off, still we might get the bowels to act for some time, and thus be able to nourish her and get her strength up to a point where an operation might be reasonably safe. She has grown thinner and weaker, however, and I do not suppose there is any chance now. I do hate, though, to go and see a patient day after day and do nothing. How successful has been the operation for anastomosis of the intestine? If any thoughts occur to you about this case, I should be glad of them.

Sincerely yours.

F. W. CHAPIN.

On receiving my answer volunteering to go to Springfield, he requested me to come. On arriving at Springfield, I received the following account of the case from Dr. Chapin, and subsequently from him an account of the convalescence which he carefully watched.

Florence B., aged ten years. The patient has never been a very strong child. During the past five years, previously to the present illness, she has had several severe attacks of bronchitis; and, during the same period, she has had, once in two or three months, sudden attacks of severe pain in the bowels, lasting from ten to thirty minutes.

The present illness began July 22, 1890. On that day I was called in great haste, and found her in a state almost of collapse, suffering intense pain in the bowels, and vomiting. A sausage-like tumor was discovered in the left iliac region, and intussusception was suspected. Rectal injections of sweet oil and glycerine were used for two days without effect. On the third day, July 24th, six half-grain calomel tablet triturates were given by the mouth, and they were followed, in the course of a few hours, by a large defecation. The sausage-shaped tumor disappeared, and the patient was soon about the house and out of doors. She did not fully recover her strength, however.

On August 10th, during my absence from the city, she was again taken with pain in the bowels, and also suffered for a few days with acute bronchitis. She was attended by Dr. Stebbins. After this attack she went along pretty well until October 4th, when the pain in the bowels came on again severely for an hour.

On the 6th of October the pain returned, with vomiting. I gave calomel and castor oil and injections of glycerine and water. The bowels moved, but not very freely.

On the 14th of October she was taken with pain and vomiting, more intense than ever. The intestines, knotted up hard, were plainly discernible through the abdominal walls. Morphine was, of course, given as usual, hypodermically. The next day, October 15th, a somewhat irregular-shaped swelling was observed, lying, not in the left iliac region, as in July, but across the abdomen above the navel. Between this time and November 1st I held several consultations with Drs. S. F. and W. H. Pomeroy and G. S. Stebbins. The pain and vomiting continued, the swelling persisted, and the bowels failed to move in spite of large injections of sweet oil, castor oil and glycerine. Calomel, sweet oil and castor oil were also attempted by the mouth, but were rejected. The patient was fed almost entirely by the rectum.

On October 20th there were two small discharges of feces. On November 4th I was again called in great haste to the little sufferer and found her in great agony, on her face and knees in the bed, and straining as if at stool. Examination revealed a piece of sloughing intestine protruding from the anus. I took hold of it and gently pulled it out. The mass had the characteristic odor of sloughing tissue and measured, when laid out, about three feet. Portions of it were mere shreds, however, and probably the actual length of intestine discharged was not more than eighteen inches.

After the discharge of the portion of the intestine, the patient was much better for a period of four days, during which time she took and retained solid food by the stomach, and the morphine was omitted. On the second day after passing the intestine the bowels moved freely.

On November 6th, four days after the sloughing mass was discharged, she began to vomit again, the abdominal pain returned, and the intestine was again knotted, as could be plainly detected through the abdominal wall. Morphine hypodermically and rectal feeding were again resorted to. Enemata of glycerine and oil, and calomel by the stomach produced no effect until December 1st when, following a dose of six half-grain calomel tablet triturates, the patient had a peculiar, flat, tape-like movement.

After this there was no discharge from the bowels, the patient retained very little by the stomach, was fed almost wholly by rectal injections, took from one-eighth to one-fourth of a grain of morphia every three or four hours, emaciated steadily and to the last degree.

The diagnosis of stricture following the sloughing of an invaginated portion of intestine had been promptly made upon the return of the symptoms of obstruction, four days after the discharge of the sloughing mass, and the question of the possibility of relief through surgical interference had been many times considered and had been presented to the family. Only feeble hopes of success by means of an operation could be held out, however, and so the case was allowed to drift on until the eleventh hour, when I became so impressed with the feeling that relief might still be had that I prevailed upon the parents to allow me to send for Dr. Romans.

#### OPERATION BY INTESTINAL ANASTOMOSIS.

On December 27, 1890, with the assistance of Drs. Mixer and Chapin, and in the presence of Drs. S. F. and W. H. Pomeroy and Dr. George S. Stebbins, intestinal anastomosis was done. Patient extremely emaciated. Abdomen at first opened between umbilicus and pubes, narrowly escaping cutting open the bladder, which was distended and drawn up. Later the opening was extended upwards. A little ascitic fluid ran out. The cecum and ascending colon and a portion of the transverse colon, filled and stuffed with feces or with rectal alimentation, presented. The cecum was about the size of the muscular part of a man's forearm. It was turned out of the abdomen to make more room, and the distended small intestine was run over until the duodenum was reached, and then, from the same point, was run over downwards to the cecum; and the obstruction was found at a point in the upper part of the ileum. Here the intestine seemed cut off down to the mesentery; there was no continuity of the bowel, but only of its mesenteric attachment. All the calibre of the bowel for a space about a line

long had disappeared, and only the mesentery and a little cord, like that between two sausages, remained. The loops of the intestine in the vicinity were somewhat adherent. With Dr. Mixer's assistance, the intestine was compressed between the thumb and forefinger above and below the points chosen for the insertion of the plates. After the anastomosis had been made according to Senn's method, the peritoneal surfaces were united around the rings by additional sutures. The abdomen was then washed out with warm water and the incision closed. During the operation much offensive gas and considerable whitish, pulaceous, offensive substance had passed per anum. The wound was sewed up and covered with iodoform gauze, absorbent cotton and a bandage.

At the close of the operation the patient was almost pulseless, and she reacted slowly, abdominal pain returning in about two hours, and free urination taking place at the end of eight hours.

On January 1st, the fifth day after the operation, the patient passed gas several times per rectum, and, on the same day, the bowels moved slightly. The swathe was changed on this day also, and the abdomen was found soft and not distended.

On January 2d, the bowels were moved by Rochelle salts.

On January 3d, the bowels moved three times freely. From that time on, the bowels moved every day or two freely, large clay-colored masses being discharged, until, by the 20th of January, the stools became normal in size and color. Meantime the abdominal pain had persisted, and the patient had vomited occasionally. Rectal injections of peptonized milk and brandy, which had been used for some days after the operation, in connection with milk punch, Kumyss and Mellin's food by the stomach, were gradually discontinued. By the middle of January the patient was taking solid food.

The pain and vomiting were very persistent, however, especially the former, and it was fully six weeks before the hypodermic injections of morphia could be discontinued. In spite of the amount of nourishment taken, the patient continued to emaciate and grow weak. At one time, early in February, she was for a few days delirious from sheer exhaustion, and for several days suffered extreme pain in her extremities. Her appetite became voracious, but the food seemed to do her no good. Her emaciation was extreme. Finally, in the latter part of February, under the use chiefly of predigested foods, she began to gain flesh, and the improvement soon became rapid.

During her long illness the legs had become so firmly flexed upon the thighs that it required several weeks of persevering effort on the part of her mother to extend them. The bony plates used in the operation were probably thoroughly digested, as nothing was seen of them in the discharges.

The little girl now weighs sixty pounds, has no intestinal symptoms, and is the picture of health.

A PHYSICIAN in this vicinity was recently called to a family, which he found in such destitute circumstances that he gave, in addition to his prescription, a five-dollar bill. Happening in the next day, he discovered that his gift had been thus spent: three dollars had gone to the priest, and two dollars to get another doctor.

## ON THE DETECTION OF A RUPTURED BLADDER.

BY ROBERT F. WEIR, M.D., NEW YORK.

IN Dr. A. T. Cabot's interesting paper on the proper treatment of a ruptured bladder, which appeared in the *Boston Medical and Surgical Journal*, October 15, 1891, he has kindly mentioned with commendation a method for detecting this injury which I reported to the profession in 1887.<sup>1</sup> But the test may be considered by many as an incomplete one, as given by Dr. Cabot.

Reference to my original article<sup>1</sup> will show that although corroborative weight is obtained by determining that the quantity of fluid thrown in the previously emptied bladder is the same in an undamaged viscus as that which flows out again through the catheter, yet this test alone is not considered by me sufficient. To be of positive service, such a test should be applied several times, and with a decided amount of distention of the bladder—this latter is not always carried out.

In sundry cases previous to 1887 I had employed this method alone, and not always with satisfaction. In one case where the total amount, five ounces, thrown in, was returned, the autopsy showed a valvular rent postero-inferiorly with moderate urinary infiltration. From this fact, together with the experience that came with the use of suprapubic cystotomy, I was led to employ in the detection of vesical ruptures the combined rectal and vesical distention, with a known quantity of water for the latter viscus. The bladder, outlined in this way above the pubis, is only to be confounded with an extravasation augmented by the test, and this is controlled by the measurement of the fluid finally emptied from the bladder. If dulness on percussion above the pubis occurs, and the fluid withdrawn from the bladder is lessened, a rupture extra-peritoneally can be inferred. If no dulness nor recognized vesical distention above the pubis takes place, but with diminution of the injected fluid, a rupture either intra-peritoneal or sub-peritoneal postero-inferiorly can be assumed. If the latter exists, a rectal examination, made before, during and subsequent to the test, will show, as it did in one case with me, the increase in the extravasation in that region.

In any case, however, where the site of the rupture cannot be determined with accuracy, it seems to me to be preferable to make an incision suprapubically, where any slight infiltration exterior to the bladder will be revealed; if this has not been torn in front or if nothing is thereby disclosed, the bladder, held up if necessary by a sound introduced per urethram, should be opened sufficiently for digital and ocular inspection. The rectal water-bag is here especially of importance to readily examine the inferior parts of the bladder.

My judgment leans, it will be seen, more to this method of procedure than to the one suggested by Dr. Cabot, of primarily opening the peritoneal cavity and exploring for the rent. I cannot think this latter plan as certain or as free from additional risk as that I have above suggested.

MEDICAL JOURNALS IN PARIS.—A report recently presented to the French Minister of the Interior states that 145 medical journals are published in Paris, whereas there are only 161 non-medical newspapers.

## Clinical Department.

### PERICARDITIS WITH LARGE HÆMORRHAGIC EFFUSION IN A PATIENT WITH GRAVES DISEASE; REPEATED PUNCTURE; DOUBLE DRY PLEURISY; RECOVERY.<sup>1</sup>

BY FREDERICK C. SHATTUCK,  
*Professor of Clinical Medicine in Harvard University, etc.*

M. P., twenty-four years old, of unimportant family and previous history, entered the Massachusetts General Hospital, January 19, 1891. About Christmas she was laid up four days with tonsillitis, at that time very prevalent in town. January 5th she began to suffer from pain and swelling in several joints, feverishness, pain in the cardiac region, and dry cough; though lame, she kept about till the 16th, when she took to bed.

On entrance to hospital the pulse was 120, respiration, 26, temperature, 103.2°. The joint symptoms were slight. The cardiac impulse was not distinct to either sight or touch; the area of dullness was moderately increased; pericardial friction was heard about the apex and also in the aortic area; the pulmonic second sound was somewhat accentuated. The first few days she seemed to improve; the temperature soon, however, began to rise steadily and reached 104° on the 27th, with a pulse of 130, regular. During the access of fever the pericardial effusion increased rapidly, the area of dullness extending from well outside the left, nearly to the right, nipple, and up to the second rib; the motion of the heart could be seen and felt, probably transmitted through the fluid, over the whole of the lower portion of this area.

January 28th. The condition seemed so critical that, after consultation with my colleague, Dr. Tarbell, it was decided to try to withdraw the fluid. A trocar and canula, attached to an aspirating pump, was plunged into the fifth left interspace, three inches from the median line, and about an ounce of bloody serous fluid was removed. No more could be got, though the canula was freely movable and unobstructed; on moving the canula adhesions could apparently be felt to break, and the action of the heart was communicated to the instrument with great distinctness. The trocar was then inserted in the fourth right space, two and one-half inches from the median line, where percussion was flat, in the hope that, in accordance with the experiments of Dr. Rotch, this might prove a more productive spot. The instrument was pretty freely movable, but no fluid was obtained. An ice bag was applied to the cardiac area.

January 29th. She was fairly comfortable with the aid of morphia. There was some return of articular symptoms. The action of the heart was irregular and intermittent. Friction was distinct over a considerable area; the extent of the dullness remained about the same.

January 31st. The urine was still intensely acid in spite of large doses of potassic citrate. Cold sponging was ordered on account of the nervous symptoms and the pyrexia, the temperature reaching 105° the evening of the 30th. That day I made her a special visit at 9.30 p. m. The area of dullness was still greater, and the impulse was distinct in the anterior axillary line and fifth space. She was dusky, and the pulsus paradoxus was marked. The trocar was inserted in the fifth left space, four and one-half inches

from the median line; only half an ounce of bloody serum could be withdrawn. An hypodermic of morphia was given.

February 1st. Condition about the same. Thinking that perhaps the heart was held above the chief part of the fluid by adhesions, and that I could possibly get in behind the organ, a trocar was again inserted, this time in the fifth space and anterior axillary line, six and a quarter inches from the median line; percussion was flat over this spot and the impulse could be felt. No fluid was obtained though the end of the instrument moved with freedom.

February 4th. The pulsus paradoxus continues; the heart is still irregular; there is no abatement of the effusion. Pleural friction is heard over much of the right chest front and back. In the afternoon sudden delirium.

Solid line, January 19th.  
Broken line, January 27th.  
Seat of puncture: No. 1, 3 inches from median line; No. 2, 24 inches; No. 3, 4 1/2 inches; No. 4, 6 1/2 inches.

February 5th. Delirium continued through night, and persists. At three in the morning the pulse was very poor and the respiration choking; the patient was in a dusky pallor and cold sweat. Nitroglycerine was given with apparent good effect. This seemed the turning point in the disease. The delirium disappeared this afternoon. The pulsus paradoxus continued for some days. A systolic murmur developed at the apex. Though very ill and weak for some time, she gradually improved, and steady absorption of the fluid took place. Pleural friction developed over the left side.

February 28th. She sat up with a bed-rest.

March 5th. She sat in a chair for an hour.

The action of the heart continued rapid, and was easily excited, but regular. About this time a slight enlargement of the thyroid gland, which had probably escaped notice during her critical illness, was observed. There was no prominence of the eyeballs, but tremor was well marked.

April 2d to 5th. Convalescence was interrupted by marked swelling of tonsils and uvula without patches.

<sup>1</sup> Read before the Boston Society for Medical Improvement, May 25, 1891.

April 12th. She was discharged, practically well, though weak. The area of cardiac dullness was but little increased; the systolic scuffle was still distinct, and will doubtless persist; all evidences of pleurisy were absent; the cardinal symptoms of Graves disease, save exophthalmos, were evident.

*Remarks.* The general treatment of the case demands no special consideration. She was at first put on my routine treatment for acute rheumatism, a combination of the alkaline and salicyl. The amount of potassic citrate which was required to make and keep the urine alkaline, was, in my experience, unusual. The salicyl was not well borne. During the period of notable cardiac weakness digitalis was used, for a time freely.

Puncture of the pericardium for serous effusion, is, I think, rarely called for; most effusions, even those of large size, generally undergoing spontaneous absorption. This seemed to be a case in which puncture was urgently demanded, and yet I cannot think that the result was much, if at all, influenced thereby. Twice fluid was withdrawn; but the amount (one ounce and half an ounce) was trifling. Why I did not get more I do not quite understand. That fluid was present in large quantity seems to me beyond reasonable doubt. Twice it was reached by a fair sized and unobstructed canula which moved freely, as if in a cavity; though once adhesions could apparently be felt to break down, the other time this was not the case.

Next, a few words as to the dry taps. This seemed a very suitable case for tapping in Rotch's spot, the fifth right space, as the pericarditis was at the time uncomplicated by either pleurisy or pneumonia. Through an error, I went into the fourth instead of the fifth space, and got absolutely nothing, although the flatness extended well beyond the point of puncture, and the experimentally distended pericardium underlies this space as well as the fifth. The puncture in the left anterior axillary line was equally fruitless. Where the trocar went on these two occasions I do not know. If it had penetrated the lung, I should have expected the suction to bring out a little frothy blood — which it did not. I certainly did not penetrate the heart itself; I am sure that I did more than penetrate the thin chest wall. The cardiac movements could be seen and felt at all the points of puncture, a fact which makes one a little nervous at first. In two cases of encapsulated and pulsating empyema this winter, I have tapped the pulsating area, both times successfully.

The paradoxical pulse did not reach its highest development in this case: that is, the slowing and weakening of the pulse were distinct to the finger during inspiration, but the pulse did not disappear during this act. This peculiar pulse rhythm is not confined to cases in which tough fibrous adhesions drag upon the aorta during inspiration; it has been observed in cases of pericarditis as well as in other and varied conditions. I have myself seen it this winter during the last hours of life in a patient who had suffered for years with asthma, and in whom the autopsy showed the heart and lungs to be free from serious organic disease.

A PHILADELPHIA man is enthusiastic over the efficacy of advertising. The day after he had inserted in a paper a notice saying that he wanted a boy, his wife presented him with twins, both boys.

## Reports of Societies.

### BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

G. G. SEARS, M.D., SECRETARY.

REGULAR Meeting, Monday, May 25, 1891, the President, DR. FREDERICK I. KNIGHT, in the chair.

DR. JOHN HOMANS presented a paper on

A CASE OF INTESTINAL ANASTOMOSIS BY MEANS OF SENN'S PLATES FOR THE RELIEF OF COMPLETE CHRONIC OBSTRUCTION CAUSED BY INVAGINATION AND SLOUGHING OF THE UPPER PART OF THE ILEUM.<sup>1</sup>

Dr. Homans stated that this method was devised by Dr. Senn, by whom the plates (samples of which were shown) were invented. Various other kinds of the same sort of thing have since been contrived. Abbe's rings of catgut, and India rubber rings have been successfully used. McBurney, Bull and other New York surgeons have done a number of cases of anastomosis between the stomach and duodenum, for cancer. I do not remember that this operation of anastomosis by bony plates is described as having been done in New England. A practical point is to make the openings in the bowel just long enough and no longer than to admit the rings, and I think it well to sew the peritoneal surfaces of the bowel together outside and around the rings. I should say that most of the anastomoses that have been done have been between the stomach and upper part of the small intestine.

DR. MIXTER: There has been a considerable number of resections done, the bone plates being used. Several cases have recently been reported by English surgeons, where the pylorus has been resected in this way. Whatever the part of the intestinal tract excised, the ends are turned in and closed by continuous or interrupted sutures, and an anastomosis is made between the two lapped ends of the intestine by means of the plates in the usual manner.

DR. HOMANS: Dr. Halstead does the anastomosis without plates. The advantage of the plates is that a person who is not accustomed to doing these operations frequently, and has not the requisite manual skill to do Halstead's operation, could do one of these operations by Senn's method without any trouble. It is a good operation in cases of malignant annular stricture of the large intestine, which are very easy to find and are apt to be simple and uncomplicated. In other cases of malignant disease of the bowel perhaps resection ought to be done in preference to anastomosis, since the latter leaves the cancer *in situ* and the former removes it. An opening can be made above and below the stricture, and a person who is expert could do it in a few minutes. The trouble with intestinal obstruction as I have seen it, is that where the coils of intestine are greatly distended, and you have hauled them over enough to find the obstruction, you have given the patient a blow almost sufficient to kill him. The sudden cases of obstruction to which I have been called have been, with one exception, cancer, and without previous symptoms, in stout people. Upon opening the abdomen and carefully searching for some time I have found a malignant stricture either at the splenic angle of the descending colon, or in the cecum, or down behind the uterus in the sigmoid flexure, and I have never be-

<sup>1</sup> See page 488 of the Journal.

fore met with so good a case as this, where the patient had no peritonitis, was healthy, and very thin, so that investigation is easy and harmless. The manner of making intestinal anastomosis varies. This is an example of Seenn's method, and is one of the most valuable inventions that we owe to this indefatigable surgeon.

DRS. G. L. WALTON and C. F. CARTER presented a paper on

THE ETIOLOGY OF EPILEPSY WITH SPECIAL REFERENCE TO INFANTILE CONVULSIONS.<sup>2</sup>

DR. WEBBER: Dr. Walton in his paper has spoken of infantile convulsions without specifying the kind and variety. A child may have a convulsion lasting a few minutes, and recover from it by treatment or without, and that be the end of it. A convulsion like that, or several of them occurring at different times, would not necessarily predispose that child to epilepsy. There is, however, a form of convulsions which are severe, the child being unconscious and convulsed for perhaps a half-hour, sometime three or four hours. In such cases I have formed the opinion—I have not seen autopsies—that the nutrition of the brain is affected, and it is such convulsions as that which I have found are followed by epilepsy, that is, epileptics who have had convulsions in infancy have had those severe forms of convulsion. I have not looked up my records; I do not know what proportion of cases I have seen with such a history, but it is larger, I think, than what Dr. Walton has found. I have noticed a good many cases of epileptics with such a history, and it is that kind of convulsion, the severe convulsion lasting a long time, frequently one or two hours, or one half-hour, and then repeated in a very short time, which affects the development of the child. I have seen quite a number of cases where the growth of one side of the child was apparently retarded in consequence of these convulsions. In one very marked case the difference in size could be measured in the head, in the arms, in the body, and in the legs, the whole of one side having been retarded in growth. In such cases there are undoubtedly changes in the brain, which give rise later to the epilepsy. I do not agree with Dr. Walton in the idea that such convulsions are not the cause of epilepsy. I think they are, and I think that it is our duty to caution parents where there are such convulsions as that, to be on the look-out for attacks afterwards. Now, in some of those children the epileptic attacks will commence very soon afterwards and continue during the rest of infancy and childhood. In other cases the epileptic attacks do not appear until perhaps the second dentition or puberty. Very often the parents have overlooked the epileptic attacks, the first form of attack being *petit mal*, and if you crossquestion them you find the child has had these attacks of *petit mal* sometime, beginning perhaps two or three years after the severe convulsions in infancy, but the *grand mal* later.

Incidentally, Dr. Walton spoke of hemierania as not running into epilepsy. Perhaps it does not run into epilepsy, but I remember one case where hemierania occurred in early life, and epilepsy seemed to take its place. I only remember one such case.

DR. PRINCE: I have very little to say. It seems to me that Dr. Walton's paper is a very valuable contribution to this subject, and goes a good way toward

refuting this popular fallacy regarding the origin of epilepsy. I confess that I myself have always accepted on faith rather than the text-books said, and assumed that convulsions in infancy did lead to epilepsy. Now looking back upon my cases, I am struck with the fact that I can recall scarcely one case in which there was a history of the convulsions dating back to childhood. I do not know that I have ever made any systematic attempt to discover whether they had convulsions in infancy followed by a period of freedom, which is one of the important points raised by Dr. Walton. It seems to me it would be very desirable for all of us in the next year or two to make a collective investigation on this subject, note our cases and see where we come out. I should really question whether very many writers have really taken the trouble to inquire into this subject deeply, and I fancy many of them have taken it on faith, as I have.

DR. KNAPP: I am disposed to agree with Dr. Walton theoretically, that epilepsy is a disease *per se*, and that it should not be confounded with convulsions which arise from hysterical causes or from organic brain disease, but unfortunately there are very many cases where we can distinguish only when we have the brain under the microscope. I am sorry that I have not been able, partly from lack of time and partly from the fact that my records are scattered, to tabulate my own cases, so that I am unable to speak from anything more than general impressions, which are altogether misleading, but I do not think, however, that my cases, or the cases in the experience of any one man, are enough to give us conclusive data upon this point. Dr. Walton mentions the physiological irritability of the infant, an irritability making him more prone to convulsions than the adult. This, of course, is to be admitted, but he speaks in a way which seems almost to compare the convulsion of the child with the perfectly normal process of regurgitation. Now I think we should draw a very sharp and distinct line between the two. The convulsion is necessarily and essentially something pathological, as of course Dr. Walton will admit, but I am disposed to lay much more importance than Dr. Walton has done upon the rather sinister significance of convulsions in the child. The latest and perhaps best treatise on epilepsy which I have seen for some time, the recent essay by Hare, admits, as do most of the writers whom Dr. Walton has quoted, the rather grave significance of infantile convulsions. I think we get a rather instructive comparison from the traumatic cases. If, for instance, the patient receives a blow upon the head—an adult with a perfectly vigorous and healthy brain—there is a fracture driving spiculae of bone into the meninges. Matters go on quietly for a good many years, in some cases twelve or fifteen years, but finally there is a motor discharge. The brain has at last succumbed to the irritation, and the discharges are repeated; the patient has convulsion after convulsion. If that case be taken sufficiently early, and the irritation be removed, the convulsions cease. But in many cases, as Hughlings Jackson has so clearly pointed out, the epileptic habit has been set up, and you may trephine and remove the irritation, but the convulsions do not cease. The same is true in some of the cases, at any rate, of convulsions in children. I believe that the ordinary infantile convulsion is a pathological thing; it is an affair of distinctly sinister significance. The common alleged causes of convul-

<sup>2</sup> See page 485 of the Journal.

sions, indigestion, teething, etc., are of course universal, but only a small percentage of the children have convulsions. That, to my mind, is distinctly significant of a more unstable brain, a more irritable brain. Now the history of these cases is often this: the child has had an attack of indigestion or a trouble with its teeth, and has a convulsion. The mother is alarmed, sends for a physician, and for the next two or three years takes distinct precautions against a repetition of the convulsion. I do not mean necessarily giving bromides, but avoiding the causes. The convulsions are not repeated. The epileptic habit is not set up. But in other cases we have different results, one case I bear in mind now, where the mother said: "O, it is nothing but a spasm. He ate something that disagreed with him"; and continued to let the child fill himself with indigestible food, and the child has had many spasms with indigestion. Such a child, I think, is liable to develop epilepsy. Although I regard convulsions as of sinister significance, I do not believe that they always mean epilepsy. They may be the indication of other affections, the early symptom of some organic brain disease. Dr. Fernald, the other night at the Medico-Psychological Society, reported that in twenty per cent. of all idiots the history began with a convulsion as an infant. I think we make a mistake; I think we do wrong to the mother to say that it may not amount to anything. I think a convulsion in a child is a serious thing. It means a more unstable and irritable brain. Such a child should be guarded against the repetition of the convulsions, against the development of epilepsy or other severe nervous diseases; we must regard that child as unstable, as irritable, and as a subject to be guarded. We must not say: "O, it is of no consequence." If we do, I fear many of these cases will go on developing either epilepsy or serious nervous disease, or, as a physician suggested to me a little while ago, in many of these cases insanity may develop later; a fact he had noted in quite a number of cases.

DR. WILLIAMS: If what Dr. Walton has said is true, I think it is a very important matter. I think where children have symptomatic convulsions it has been the practice among general practitioners to fear epilepsy may possibly result, and put them on a preventive treatment, and I have seen harm where that treatment has been applied. In some cases the children have been kept back from school, and kept on a vegetable diet, no meat given them. I have seen one or two cases treated with that idea by specialists, having been treated with the bromide mixture a long time. I know one little girl who was treated by a specialist in Boston over ten years with bromides off and on, and never had but one convulsion, and I thought when I saw her that her mind was undoubtedly somewhat weakened, whether due to the bromides or possible nervous disease, I cannot say. She seemed to improve after the bromides were given up. It seems to me Dr. Walton's suggestion to disregard this preventive treatment awhile and try the result, is a thing well worth considering.

DR. WEBBER: I would like to ask Dr. Knapp whether Dr. Fernald stated how many of these idiots from convulsions had epileptic attacks.

DR. KNAPP: I don't remember that. I understood that in a part of them the idiocy began with convulsions. Many of the idiots were not epileptic. Of

course there is a large percentage of epileptic idiots besides.

DR. WALTON: It is a very curious fact that out of seventy cases the five which had infantile convulsions did not have those severe convulsions which Dr. Webber associates with future epilepsy, but were merely spoken of as having ordinary infantile convulsions. It seems to me in Dr. Webber's remarks that he was perhaps a little inclined to consider organic brain disease with convulsions, as epilepsy. He speaks, for example, of unilateral lack of nutrition resulting. Now we know that in cases of hemiplegia resulting from hemorrhage in infancy, or thrombosis of the veins emptying into the longitudinal sinus, we may expect convulsions. In that case it is an organic disease that produces the convulsions, and I should not class them under true epilepsy.

In regard to the connection between migraine and epilepsy, it is true that there is some analogy between them. The two diseases are both spasmodic, and both produced sometimes by similar causes. I am convinced, for example, that errors of refraction are the most common causes of migraine, and occasionally I think a case of epilepsy is relieved by putting on astigmatic glasses.

In regard to the importance of distinguishing true epilepsy from the convulsions resulting from organic disease, I think it is important to distinguish them as accurately as possible in order that our ideas may be accurate for just such investigations as the present one, which have a practical value. The exact pathology of epilepsy and migraine is less important for practical purposes than the question should a person who suffers from migraine be told he is in danger of having epilepsy. This is a vital question for all of us, just so in the case of these children with infantile convulsions: Are they liable to produce epilepsy later in life? It seems to me Dr. Williams has touched the practical side of the question in asking if a child should be put on preventive treatment (bromides) because he has had a convulsion.

DR. KNAPP says truly the experience of any one man is not enough to absolutely establish the facts, but it seems to me the results of our investigations have been printed enough to make us chary of accepting the traditional views, and I am very much in hopes, as Dr. Prince has suggested, that collective investigations may be made on this point. When Dr. Knapp speaks of the sinister significance of convulsions, he alludes to the small percentage of children who have infantile convulsions. I have been surprised, on the other hand, at the large percentage in our investigations, about one in ten, certainly not as many as regurgitate their food in infancy, but sufficient to make the process seem rather analogous.

We have endeavored to remove from the statistics all cases where I could find any organic disease, any fever, or anything of that sort in the general condition, and have tried to consider only those convulsions that were so-called infantile convulsions, pure and simple.

DR. F. C. SHATTUCK reported

A CASE OF GRAVES DISEASE WITH ACUTE PERICARDITIS, PARACENTESIS OF THE PERICARDIUM. RECOVERY.<sup>3</sup>

DR. MASON: I should like to ask Dr. Shattuck if

<sup>3</sup> See page 491 of the Journal.

other cases have come to his observation where the pericardium had been tapped successfully.

DR. SHATTUCK: I think one, and there we wanted to go in on the right side, but there was pneumonia, solidification of the lower portion of the right lung, so that we could not. I have seen one other case where tapping was not practised, but thought of. There was a complication of a similar kind in that case.

DR. MASON: Since Dr. Rotch's monograph was published the physicians at the City Hospital have been looking out for cases in which that method might be applied, tapping in one of the right spaces, fourth or fifth. No such case has yet been found, I think; and indeed I am not aware of any case of tapping of the pericardium which has been practised. I have never seen it done myself with the exception of one case of doubtful diagnosis, in which I tapped the left side of the chest in the mid-axillary line. It appeared at the post-mortem that the pericardium had been punctured. The puncture, however, did not produce any special result on the progress of the case. The patient died of fibroid phthisis with pericardial effusion which was not diagnosed with certainty. In that case the puncture did no harm and no good, and was mainly accidental; so that I have no experience in the matter at all. It must be a rare condition that involves the necessity of puncturing the pericardium. The cases of hydropicardium from Bright's disease probably occur so late that it would not be of much service.

DR. WILLIAMS: I once punctured the pericardium in Bright's disease in a moribund patient, and got quite a quantity of fluid, but it did no good and I hope it did no harm. I punctured in the left side. I argued that if you punctured the right side that quite a quantity of fluid of the pericardium would retreat before the trocar, and you would not get so much fluid as on the left side.

DR. KNIGHT: I never have seen a case where I felt any operation was demanded. I have never seen the operation done.

DR. SHATTUCK: I recall a case tapped by Dr. Tarbell. The diagnosis was made of probable purulent pericarditis. It was in a case of phthisis. The man's lungs were riddled. Dr. Tarbell tapped on the left side and got plenty of pus.

DR. KNIGHT: I think that point of tapping on the right side being likely to be followed by retraction of the pericardium, is a very good one. I do not see why that is not a very proper objection to make to it.

DR. SHATTUCK: I did not go in in Rotch's spot at first, because I did not want to run any risks, and I thought I stood the best chance on the left side. When tapping on the left side was so unproductive, I then tapped on the other side, and it was practically Rotch's spot which was selected. If the effusion is large the fourth space is underlain by the liquid as well as the fifth.

POLITICAL ACCIDENTS IN IRELAND. — During the campaign enthusiasm in Cork last week among the Parnellites and McCartys there were ninety-two surgical cases admitted to the wards of the hospital, besides a much larger number of minor injuries treated in the out-patient department. The principal causes of the accidents were brick-bats, stones and blackthorn sticks.

## AMERICAN ORTHOPEDIC ASSOCIATION.

(Concluded from No. 18, page 472.)

THE Fifth Annual Meeting of the American Orthopedic Association was held at the Arlington Hotel, September 22-25, 1891. Dr. A. B. JUDSON, President; Dr. JOHN RIDLON, Secretary.

### THIRD DAY.

#### MALIGNANT DISEASE OF THE VERTEBRÆ.

The President, DR. JUDSON, reported three cases, simulating Pott's disease so closely that the wrong diagnosis had been made in all but one of them. The patients were four-and-a-half, thirty-five, and forty-two years of age respectively. The chief points for differential diagnosis are: (1) deformity present in Pott's disease, absent in malignant disease; (2) local disability; (3) local pain, both absent in caries and present in malignancy.

DR. WILLARD, DR. GIBNEY, and MR. HOWARD MARSH all spoke of malignant cases.

#### THE PROGNOSIS IN POTT'S DISEASE.

DR. KETCH, of New York, had learned from seventy-five cured cases, that in length of treatment and degree of deformity, the upper region of the spine is most favorable, and the middle least of all, that paraplegia more frequently accompanies disease in the upper than in the lower region, and that cases of traumatic recover sooner than those of tubercular origin. Sudden deaths will sometimes occur from interference with respiration.

DR. MADRA, of Galveston, Texas, proposed

#### THE TREATMENT OF POTT'S DISEASE BY WIRING THE SPINOUS PROCESSES.

He had successfully tried this procedure on a case of broken back, and was anxious to use it for caries of the spine. His method consists in laying the processes bare and winding several turns of silver wire around them, to immobilize them and prevent trauma from friction. The patient should be kept in bed for a short period of weeks, after which he can go about with a support.

#### THE OPERATIVE TREATMENT OF SPINAL CARIES,

by DR. DEFORREST WILLARD, of Philadelphia.

He divides the indications for operating into three classes: (1) to evacuate pus; (2) for the removal of dead bone; and (3) to relieve paraplegia. In speaking of the evacuation of pus, he said that the old fear of sepsis had been removed by the aseptic surgery of to-day. The situations of abscesses vary, and consequently our treatment must; aspirating is of use chiefly for diagnosis, the unusual cases of cure being cases of liquefied caseous material in a tolerably pure state. He injects an emulsion of iodoform into the cavity after aspirating; great care must be used not to needlessly lacerate the lining wall of the abscess. A free incision is preferable, and the evacuation should be thorough so as to be rid of all the pus; afterwards, the incision may be sewed up tight, leaving twenty to sixty grains of iodoform in the cavity. When within easy reach of the knife, it is well to dissect out all the abscess wall, or get rid of it by curetting, using for this purpose an irrigating nozzle with a sharp spoon attached. He has used hydic peroxide with success in some spinal abscesses.

In regard to operations for the removal of dead bone, with our present limited knowledge it must be regarded as unfeasible, except for a few selected cases of caries of the processes and arches of the vertebrae. In these the advantage of dependent drainage is also secured, and the removal of the dead bone shortens the period of suppuration.

Operating to relieve paraplegia should be considered unjustifiable in most cases, because the condition is a true pressure-paralysis from inflammatory or caseous deposits in the tissues surrounding the cord, and as these deposits undergo absorption the patient recovers the use of his limbs; hence laminectomy to relieve paralytic symptoms is restricted to a very few cases. In performing the operation it is better to divide the first lamina with a small Hay's saw, after which the others may be easily detached with bone-cutting forceps. Laminectomy is best done in the upper dorsal region; in the lumbar operation the incision is necessarily very deep, and it is hard to secure a dry wound.

Dr. KETCH referred to the careless way in which some cases were reported as cured of spondylitis, when in reality all that the writer meant was that the abscess had closed. He is anxious to have some more positive indications and contra-indications for doing laminectomy.

Mr. HOWARD MARSH, of London, made some remarks on

#### PARALYSIS IN POTT'S DISEASE.

After alluding to the occurrence of this symptom, most commonly in dorsal caries, he said that it might be due to: (1) abscess within the spinal canal; (2) softening of the spinal marrow; (3) pressure of the arches on the cord at the kyphosis, and (4) to inflammatory products and thickening of the spinal meninges. Of these, abscess is very rare, and it would be usually impossible to make a diagnosis of it, while the last-mentioned cause was certainly present in almost all cases. He, however, thought that a laminectomy done simply for exploration was only justifiable in some few instances: that, if a child with spinal caries had paralysis, it was not at all unusual for it to have recurrent attacks; but that permanent paraplegia resulting from this cause was rare; and he concluded by referring to a boy with spondylitis and paralysis of both arms and legs, who recovered the use of his limbs after laminectomy had been advised but not performed; and from this patient he had learned not to operate unless he had well tested that the condition would not improve under milder measures.

Dr. W. N. BULLARD, of Boston, read a paper on

#### SPASTIC PARALYSIS IN CHILDREN,

written jointly by Dr. C. L. SCUDDER and himself. After briefly defining the condition as one of cerebral origin, Dr. Scudder called attention to the uselessness of attempting to treat these cases by drugs, forcible correction under anesthesia, and mechanical appliances; while, so far as he is aware, uniform success has attended all the cases on which a tenotomy or a myotomy has been performed. He reports one case complicated by hydrocephalus, spina bifida, and lateral curvature of the spine, which illustrates the good effect of open division of all shortened tissues, fascia, tendons and muscles (the latter divided close to their tendinous insertions).

Dr. Bullard, in his portion of the paper, tells us that in anterior poliomyelitis there are frequently muscular

"contractures," that is, simple permanent shortening of a set of muscles whose opponents are paralyzed; while in true spinal spastic-paralysis due to degeneration of the lateral columns of the cord (and generally to a transverse myelitis as well), there is more paresis associated with the spastic rigidity than in those cases which are of cerebral origin (commonly due to intracranial hemorrhages), which class alone includes about all the spastic paralyses seen in children. The question of the possible causative agency of the spina bifida in the case reported by Dr. Scudder is interesting; it is certainly very rare to find the spastic condition associated with this deformity, while on the other hand true paralyses frequently occur. If the spina bifida be disregarded, the spastic condition is probably due to the hydrocephalus, although it is said to occur less frequently in the idiopathic variety, which was present in this case, than in other forms of the affection. Dr. Bullard has the notes of another case in which these two conditions were associated; the spastic symptoms did not appear until the child was nine years old.

Dr. BARTOW, of Buffalo, read a paper on

#### THE TREATMENT OF POTT'S DISEASE, WITH SPECIAL REFERENCE TO THE EARLY STAGE.

The early treatment should attempt to stay the spread of the process by giving rest to the affected parts. Delays are dangerous, and it is sometimes very hard to make an early diagnosis because the practitioner is looking for symptoms which should appear later on. Muscular fixation of the spine is at first apparent only when certain positions are assumed, or at certain times of the day.

Lateral distortion is the expression of ositic pain and tenderness; there is a reflex spasm of the dorsal muscles of one side, and frequently a distinct lateral curvature. For the treatment of early cases immobilization is to be aimed at by several different methods; in cases below the fifth or sixth dorsal vertebrae by recumbency or the plaster jacket; the former is often inefficient among the poor on account of their unwillingness to confine the child's movements, and Dr. Bartow applies a plaster jacket in such cases more often than he used to do. It also corrects the lateral distortion. He often uses a leather jacket made from a plaster jacket cast; these should always be removed and applied with the child recumbent; they must be watched to see if they fit, and should be worn at least one or two years, leaving the support off gradually.

Mr. HOWARD MARSH, of London, read a paper on

#### POTT'S DISEASE IN MIDDLE AND ADVANCED LIFE.

He began by a few remarks on the relative frequency of surgical tuberculous at different ages. By far the greatest number of spinal cases fall between the ages of three and ten; but he knew of a few cases in infants under one year, and two cases under eight months. It is relatively infrequent between thirty and sixty, although he had noticed its occurrence in three pregnant women aged thirty-two, thirty-eight and forty, and in two unmarried women, one forty-two, the other forty-eight; and also in an unmarried man of forty-two. He quotes from "Studies from Old Case-books," by Sir James Paget, referring to what he calls "Old People's Struma," that is, surgical tuberculous occurring after sixty; and mentions a number of cases in the hand, foot, knee and hip, in patients of this age. Pott's disease is, however, rather uncommon

mon among the old people, and he only knows of four undoubted cases: First, seen by him in consultation at St. Bartholomew's Hospital; second, seen in private practice; third, a case recorded in Sir James Paget's work previously referred to, and fourth, a pathological specimen in the Museum of the Royal College of Surgeons.

DR. L. A. WEIGEL, of Rochester, delivered a paper on

#### CERVICAL SPONDYLITIS.

He reports an interesting case of this affection, complicated by prolonged paralysis and a deep cervical and retro-pharyngeal abscess, and calls attention to the fact that in this case extension by weights in bed had immediately made the patient comfortable, and had speedily relieved the paralytic symptoms which recumbency alone had failed to benefit. Although paralysis and abscess are commonly developed in cervical cases, it is unusual to find them occurring together in the same patient, and it is an interesting question whether the abscess would have occurred if traction had not been employed.

After a half-hour's recess, the Section listened to

#### RECUMBENCY IN POTT'S DISEASE,

by DR. AP MORGAN VANCE, of Louisville.

Dr. Vance called attention to the good obtained by temporary recumbency. Surgeons often overlook this, but benefit is frequently seen where mechanical treatment has failed to relieve the symptoms, or when the circumstances prevent the proper application of protective apparatus. The usual objections are made on the plea that the general health will suffer, but he has yet to see bad results from it. The children usually improve in this respect, particularly with attention to proper feeding and with massage to the extremities, when this has been necessary on account of paralysis or other intercurrent disease. There is often rapid improvement of the bone lesion. He believes that the turning point in the disease often followed this temporary recumbency.

DR. CHARLES C. FOSTER, of Cambridge, then read a paper on

#### EXTENSION IN BED.

After alluding to the necessity for rest and for avoiding traumatic influences affecting the diseased vertebrae, he speaks at some length of the injury done by forcible and violent movements recklessly inflicted by ignorant friends or by a quack, with the view of "curing a stiff neck or a stiff back," and illustrates his remarks by the exhibition of a pathological specimen from the Warren Museum, and the report of a case of a boy who had been under his care at the Cambridge Hospital. In both instances the neck had been twisted to remove the stiffness, and trouble had followed.

In regard to the method of applying extension, the child is first secured on his back in bed on a frame, and weights are attached by means of cords running over pulleys to a waist-belt or a chest-belt, while another weight is connected by means of a cord and pulley at the head of the bed to a "hat-band extension strap" similar to the one used by Dr. Sayre. To obtain good results this treatment should be begun early in the course of the disease, and should be persevered in for a long time.

Dr. Foster has found the following method of pal-

pation of the spine of service in locating the seat of the curious process before a kyphosis appears. The child lies on its face, and the physician places the thumb of one hand firmly on the spinous process of a vertebra, while the tip of the index-finger resting lightly over the next spine notes any movement between the two which he may impart with his other hand; this process is repeated all the way down the back, and the amount of motion between each pair of vertebrae may be determined with tolerable accuracy after some practice. Disease of one vertebra may affect only one or both intervertebral joints; in the earliest stage the mobility is increased, later it is much diminished by the inflammatory infiltration of the joint and surrounding tissues, and is finally lost when ankylosis takes place. The value of the treatment by prolonged extension and recumbency depends largely upon constant medical care and good nursing; and if these cannot be had, it is wise to resort to another method.

DR. REGINALD H. SAYRE, of New York, then followed with a paper on

#### TRACTION AND FIXATION IN POTT'S DISEASE.

He said, briefly, that all that rational treatment in spinal caries could expect to do was to avoid traumatism from movements of the spine, from the crushing weight of the superposed parts of the body, and from the reflex spasm of the muscles. That traction relieves pain in all joint-disease is well illustrated by the ordinary effect of the application of a jury-mast, namely, that it very quickly stops the pain. Dr. Sayre believes that for most spinal cases all indications are fulfilled by the continued use of the plaster jacket properly applied and watched. If paraplegic symptoms come on, they should be treated by traction, and operative interference should be restricted to a very few cases.

#### THE COMPARATIVE VALUE OF PRESENT MODES OF TREATMENT OF CARIES OF THE SPINE,

by DR. E. H. BRADFORD, of Boston.

The treatment of caries of the spine necessarily must be based on the pathological conditions, and as these vary the treatment must necessarily vary. The methods should also be adapted to the portion of the spinal column affected, for caries of the spine differs somewhat in its course in different portions of the spinal column.

The methods of treatment may be grouped as follows: treatment by recumbency, treatment by mechanical appliances, and treatment by plaster bandages and corsets.

Of the treatment by recumbency, it may be said that it is of great value in the acute stages, and is indicated wherever the patients find great disability in going about, and are disinclined to walk or run, and are more contented when lying or sitting down. Recumbency should, however, be thorough; the patient should be kept upon the back, with proper arrangements of pads, so that sloughing should be prevented; and the patient should be fixed by means of a frame or straps, so that no sitting up or turning in bed should be possible. It should also be arranged so that the patient can be carried about freely, so as to be given the benefit of fresh air. Traction by weight and pulley, applied to the limbs or to the neck, is sometimes of great assistance. The necessary limits to the benefit

to be derived from recumbency are determined by the patient's general condition. It is manifestly impossible that the patient should remain in the recumbent state until the cicatrization has taken place, as this process involves years. For this reason the treatment by recumbency is only the treatment of a stage. Where patients begin to appear apathetic, listless; where general nutrition seems to fail after they have been kept recumbent for a long time, this treatment should be discontinued. Recumbency, by which is meant fixation, will be found to be the most efficient way of preventing increase of the curvature.

Mechanical appliances are an essential part of the treatment of caries of the spine; for whether recumbency is used or not, at some stage some form of mechanical appliances, either a corset or a brace, must be used in order to enable the patient to go about without danger to his back.

The form of mechanical appliance will necessarily vary according to the region of the spine affected; but a mechanical appliance based upon the principle of the antero-posterior supports is what the writer has found most serviceable. Where head-supports are necessary, the writer uses both the jury-mast, the wire chin-support, the Thomas collar, or the Taylor oval ring; the latter being, on the whole, preferred in a majority of cases where care can be given in adjusting it. The jury-mast is equally efficient, but has the disadvantage of unsightliness.

Treatment by mechanical appliances has the disadvantage of requiring skill and experience on the part of the surgeon, and attention on the part of the parents. It can, however (given these conditions), furnish the most efficient of means of treatment with portable apparatus; and patients can be thoroughly treated in this way, in many instances, without recumbency at all.

The value of plaster jackets is very great, and for the ordinary treatment of hospital cases, where great care cannot be given by the parents, the plaster jacket alone may be considered the most ready means of treatment. The writer, however, thinks that plaster jackets require skill and care to apply them properly, and they have the disadvantage of uncleanness and discomfort. The split corset, leather corset, wood corset, or cloth corset stiffened by wire, is of value in the stage of convalescence, the latter being of the least value; but in the acute stages the permanent corset is preferable.

In conclusion, it may be said that caries of the spine is the most curable of affections, but requires treatment for a long time to insure a perfect cure, the disease running its course in from three to five years. In its treatment recumbency, mechanical appliances, and the use of corsets (including plaster jacket) are all of value, and may be needed severally in the treatment of any case.

#### FOURTH DAY.

DR. GIBNEY, of New York, read

#### A FURTHER CONTRIBUTION TO THE TYPHOID SPINE,

reporting the details of another case of this unusual affection in a man now forty five years old, who, unlike the cases previously reported by the writer, exhibits a marked deformity in the cervical region dating back to typhoid fever at the age of twenty-two. Two years of pain and disability had immediately succeeded the typhoid attack.

DR. B. E. HADRA asked if the backache so constantly seen in the course of the fever was in any way due to this affection, and alluded to an epidemic of typhoid characterized by great pain and tenderness over the vertebrae.

DR. R. H. SAYRE suggested that the condition Dr. Gibney described might be analogous to the arthritis of typhoid in other joints.

DR. BENJAMIN LEE, of Philadelphia, gave in a few words

#### A BRIEF HISTORY OF THE USE OF SUSPENSION IN POTT'S DISEASE.

After referring to the very mixed state of our knowledge of scoliosis and spondylitis thirty years ago, and the frequency with which they were confounded with each other, he said that he had applied suspension to a case of Pott's disease as early as 1865, and in the following year had exhibited his apparatus (a jury-mast attached to a chair) for which he had obtained a prize. Dr. Lee claims to be the originator of self-suspension in the treatment of lateral curvature and also for the purpose of correcting the lateral deformity of spinal caries. The remainder of the paper is devoted to ancient machines for suspension, and is interesting from a historical point of view.

#### THE TREATMENT OF CONGENITAL DISLOCATION OF THE HIP,

by DR. E. H. BRADFORD, of Boston.

Dr. Bradford showed photographs of appliances for the treatment of a case of double congenital dislocation of the hip-joint, which for the last three years has been treated according to the method of Dr. Buckminster Brown. The modifications from Brown's method were such as to allow the patient to be carried about, though not allowed to stand. At the present time the patient is allowed to walk about, wearing protective appliances such as are used in convalescent stage of hip disease by Dr. Taylor. These appliances are made of aluminum, and for this reason are light. The result so far has been that the trochanter has been brought down from its position upon the ilium three quarters of an inch, and has remained in this position. The patient is beginning to walk about. There is at present some lordosis, but the lateral gait has entirely disappeared. Treatment so far has been indicative that success could be attained by this method, if care is given as in the case reported by Dr. Brown.

DR. NEWTON M. SHAFFER, of New York, read a paper entitled,

#### ELONGATION OF THE LIGAMENTUM PATELLÆ AS A FACTOR IN THE PRODUCTION OF CERTAIN KNEE-TROUBLES AND DIFFICULTIES IN LOCOMOTION,

giving the details of six cases.

The average length of this ligament in the adult was a little less than three inches, although anatomists appear to vary a good deal in their measurements. Dr. Shaffer measures from the summit of the tubercle of the tibia to the lower border of the patella with the knee flexed at a right angle. The symptoms of these patients varied from a simple weakness which prevented playing lawn-tennis, but gave no trouble in any other way, to a permanent, irreducible, outward dislocation of the patella together with a growth of osteophytes in the intercondylar notch, and this causing so much disability and atrophy of the muscles that

the case had been treated for one of "paralysis." As to treatment in the milder forms, Dr. Shaffer had applied a pad to prevent outward displacement of the knee-cap and some apparatus to slightly restrict the motion of the joint; in the severer ones fixation was tried, and an operation advised to shorten the ligament (it had not been performed in any of these cases). Where there was a large mass of osteophytes in the intercondyloid notch, it was useless to attempt to reduce the displaced patella unless these were first removed.

In discussing the paper, Dr. VANCE said that he thought joint fixation was indicated in the hope that nature would shorten the ligament just as it sometimes did in a flail-like joint, if a good splint was perseveringly worn.

Dr. GIBNEY said that he had tried this method unavailingly in one case at least, and that he was now trying to effect a shortening by injecting alcohol into the ligament in order to set up a sub-acute inflammation.

Dr. BEELY asked if these patients could voluntarily dislocate their patellæ.

Dr. SHAFFER said they could not; that the lengthened ligament allowed some rotation and a little lateral motion in the knee.

Dr. Wm. E. WIRT, of Cleveland, exhibited

#### A NEW APPLIANCE FOR OBTAINING EXTENSION,

in which the to-and-fro motion of a lever is changed into a rectilinear lengthening of the splint without any key or screw-driver.

Dr. SAYRE said that the device gave accurate and easy adjustment in the direction of traction, and would probably work very well on hip splints; the only drawback to its use was that you could not diminish the amount of pull gradually, and he hoped that it might be modified so as to overcome this mechanical defect.

Dr. ROYAL WHITMAN, of New York, made some

#### OBSERVATIONS ON TORTICOLLIS, WITH PARTICULAR REFERENCE TO THE SIGNIFICANCE OF THE SO-CALLED HÆMATOMA OF THE STERNO-MASTOID MUSCLE.

In order to investigate the influence of this affection as a factor in producing torticollis, the writer had searched the record-books of the Hospital for Ruptured and Crippled in New York, and of eighteen cases of hæmatoma there recorded he was able to ascertain the present condition of nine, none of whom had wry-neck. Another observer had similarly investigated six other cases, making a total of thirteen, all with the same negative result; hence he infers that the lesion is a possible, but certainly an unusual cause of this deformity. On the other hand, a perusal of the histories obtained from 264 patients treated at the same hospital for torticollis, shows that the mother's statement is frequently insufficient to decide whether the case was congenital or acquired. The fact remains that many cases of congenital wry-neck are still of cause unknown, although the writer believes that most of them are of intra-uterine origin—arrest of development of a muscle, etc. An analysis of all the 264 cases shows that the deformity is rather more common in girls, and that the two sides of the neck are equally liable to be affected. In more than one-half of the patients it was due to cervical adenitis, or some painful condition of the neck. Early cases should be

treated mechanically to secure rest and prevent deformity, and symptomatically to relieve the adenitis, etc.; later, free and complete division of all contracted parts should be done by open section, and the after-treatment should be carefully looked to.

In discussing the paper, Dr. HOFFA, of Würzburg, said that, in order to be sure that the deformity was of foetal origin, we should know that the accoucheur had found that the baby not only had wry-neck, but that it also exhibited an asymmetry of the face and head. He believes this asymmetry to be of greater diagnostic value than the position of the head, because, if present, it is fair to assume that the deformity has existed for some length of time. Hæmatoma of the sterno-mastoid is caused during childbirth by excessive forced flexion of the head, the chin impinging on the muscle and injuring it, and probably damaging branches of the spinal accessory nerve at the same time.

Dr. HADRA, of Galveston, said that he had removed by open section from two children, one of whom was six weeks old, masses of fibrous tissue in the bellies of the affected sterno-mastoids, which under the microscope proved to be composed of very dense cicatricial tissue, so that they must have been there before birth; he regarded it as the scar resulting from an intrauterine rupture of the muscle. This is a rare cause of torticollis.

Dr. SHAFFER said that perhaps two-thirds of all cases were congenital; most of them due to arrested development, as was shown in a patient where he had measured the sterno-mastoid at the age of six, and again at sixteen, and there had been no growth.

Dr. RYAN, of Cincinnati, reading on

#### RHEUMATIC SPONDYLITIS,

commented on the scarcity of articles relating to this affection in English and American medical journals, and hoped that the reports of more cases would be published. French writers regard it as a form of gonorrhoeal rheumatism. The symptoms are very like the early stage of Pott's disease, but the kyphosis, when it appears, is like the stooping of old age. The gait is peculiar, as if carrying a heavy burden on the back. The prognosis is not good for recovering a supple spine, and most cases suffer considerable pain for many months. It should not be confounded with rheumatoid arthritis of the spine. The treatment should first be directed to relieve pain by a support, cantharids, and medication; later, mobility should be aimed at by passive motion and suspension. Dr. Ryan reports one case.

Dr. KETCH thinks a well-fitting brace necessary, on the ground that reflex rigidity is nature's call for a splint.

Dr. HODLEY called attention to the fact that several different affections are classed under the head of rheumatism.

DRS. VANCE, BARTOW, and GILLETTE had all seen similar cases, and Dr. LEE spoke of the gouty spine, an infrequent affection resembling the rheumatic form.

Dr. GIBNEY attempted to give

#### THE DEFINITION AND SCOPE OF ORTHOPEDIC SURGERY,

as follows: "Orthopedic surgery is that department of general surgery which includes the prevention, the mechanical treatment and the operative treatment of chronic or progressive deformities."

DR. SHAFFER defined it as "that department of general surgery which includes the prevention, the mechanical treatment, and the operative treatment of chronic or progressive deformities, for the proper treatment of which special forms of apparatus or special mechanical dressings are required."

DRS. WHITMAN, FOSTER, KETCH, RYAN, STEELE and SAYRE took part in the discussion.

#### MEANS OF RECORDING ROTATION IN LATERAL CURVATURE.

by DR. E. H. BRADFORD, of Boston.

Dr. Bradford showed photographs of the method of recording rotation in lateral curvature. After describing the different methods in use, he illustrated by photographs, a method by which the cases could be recorded rapidly and with simplicity.

#### MODIFICATIONS IN THE TREATMENT OF LATERAL CURVATURE.

Dr. Bradford also showed photographs of appliances to increase the flexibility of the spinal column in lateral curvature as a preliminary exercise to the use of plaster-of-Paris bandages or other corsets.

Both of these papers were much curtailed to give time for Dr. F. BEELY, of Berlin, to read his article on the

#### PATHOLOGICAL ANATOMY OF LATERAL CURVATURE OF THE SPINE.

Dr. Beely said that the spinal column was essentially made up of an anterior column of vertebral bodies and a posterior one consisting of the arches; that the bodies connected by the compressed and elastic intervertebral discs, are always trying to expand and make the spine longer, while the stretched and elastic ligamenta subflava tend to shorten the posterior column, so that if the two halves were divided by a saw there would be almost six inches difference in length between them. This difference is greatest in the dorsal spine, less in the lumbar, and least of all in the cervical; only the lumbar spine is affected by the body weight in health. Changes in the form of healthy vertebrae occur from weight and from other causes slowly by changes in the ossification, not from rapid moulding like clay; where there is traction, other things being equal, the bone will grow, and conversely with pressure it will dwindle. Arguing on this principle, he showed, on models made of soft rubber, how the various deformities of the bones were produced, and why we should always find deformities of the same sort in definite parts of the altered column. Rotation, he thinks, is chiefly due to the different character of the anterior and posterior halves of the column; he also shows how certain deformities are produced in the transverse and spinous processes, which, together with rotation, bring about the broad and shallow paraspinous groove on the concave side of a dorsal curve, and the very narrow and deep groove on the convex one, while in lumbar curves the condition is reversed owing to the absence of ribs.

The following papers were read by title on the last two days of the meeting: "Pott's Disease in Adults," by Dr. A. J. Steele, of St. Louis; "The Prevention of Unnecessary Deformity in Pott's Disease," by Dr. Royal Whitman, of New York; "Extension in Pott's Disease," by Dr. C. E. McKenzie, of Toronto; "The Treatment of Pott's Disease," by Dr. V. P. Gilney,

of New York; "The Relations of Lateral Curvature of the Spine to Flat-Foot," by Dr. Paul Redard, of Paris; "A Contribution to the Etiology of Lateral Spinal Curvature," by Dr. C. L. Scudder, of Boston; "Spastic and Infantile Paralysis," by Dr. DeForrest Willard, of Philadelphia; "The Operative Treatment of Spastic Paralysis," by Dr. L. A. Weigel, of Rochester; "Additional Notes on Sacro-Iliac Disease," by Dr. Benjamin Lee, of Philadelphia.

### Recent Literature.

*Diseases of the Digestive Organs in Infancy and Childhood.* With Chapters on the Investigation of Disease; the Diet and General Management of Children, and Massage in Pædiatrics. By LOUIS STARR, M.D., late Clinical Professor of Diseases of Children in the Hospital of the University of Pennsylvania; Physician to the Children's Hospital, Philadelphia; Consulting Pædiatrist to the Maternity Hospital, Philadelphia; etc. Second Edition, illustrated. Philadelphia: P. Blackiston, Son & Co. 1891.

This second edition of Dr. Starr's book is like the first, most attractive in appearance, and has been much improved by being cut down in size. Many changes have been made in the text to keep it abreast of the times; and, with few exceptions, mostly points already spoken of in the previous review, the author has presented to us a most readable and in the main reliable book. The old ideas regarding the action of alkalies and cereals on the albuminoids of milk are still accepted by the author, notwithstanding that the latest investigations have proved them to be of ureal value.

We are not ready to agree with the author that wet nurses should be discarded, but congratulate him on his success in bottle-feeding. We are glad to see that the analyses of Vernois and Becquerel have been replaced by others which are more nearly correct, and it would be well for advance in infant feeding if other writers would follow Dr. Starr's example.

Excellent and instructive chapters have been introduced on "The Second Dentition" and on "Massage."

It would seem as though the surgical treatment of chronic tubercular peritonitis by laparotomy should find a place in the last chapter of the book; but it is not even mentioned.

*Studies in Pathological Anatomy.* By FRANCIS DELAFIELD, M.D., LL.D. Vol. II, Part 4. Chronic Bright's Disease, Plates LXXIII—CXXXIII. Wm. Wood & Co.

This completes the record volume of these studies, and takes up the subject of chronic Bright's disease, the difficulties of which are fully realized by the author. He divides the kidneys included in this group under four heads, from a combination of the clinical features with the anatomical appearances. But he appreciates the difficulty of drawing hard and fast lines, and realizes that very different clinical pictures may be presented at different times in a case where the anatomical conditions must be the same or but very slightly different.

This division is into chronic congestion of the kidneys,

chronic degeneration, chronic diffuse nephritis, with or without exudation of serum into the tubules. Under these he thinks all the chronic cases can be classed, and gives examples from his private and hospital practice.

The illustrations are of the same general character as in the preceding numbers, and are of a high degree of excellence. They are clearer than those of the first part and show remarkably well the points which he intends to bring out.

As completed the work is certainly a remarkable one, and a monument to the zeal and perseverance of its author.

*Practical Pathology and Morbid Histology.* By HENEAGE GIBBES, M.D. Lea Brothers. 1891.

In the first part, on practical pathology, are given the various ways of hardening, staining and mounting specimens for microscopic examination. In the second, an account of the methods employed in the culture, separation, staining and inoculation of bacteria; while the part on morbid histology is devoted to a description of the appearances that are seen on microscopic examination in diseased tissues and organs. The chief value of the book is as a guide to a laboratory course, and for this it is well adapted as it bears the stamp of the author's experience in teaching and embodies the results of his own research. There is a great deal of real worth in this, especially the result of his experiments in staining with aniline colors, to which he has devoted much time and attention.

The closing chapter deals with practical photography, especially in connection with the microscope. We cannot agree with him, however, in thinking that the illustrations, which are reproductions of microphotographs, convey as good an idea of the picture seen through the microscope, as a faithfully executed drawing. For the camera can reproduce but one plane, and cannot give the impression of superimposed images that comes from the rapid use of the fine adjustment.

*Ministering Women. The Story of the Royal National Pension Fund for Nurses.* By GEORGE WILLIAM POTTER, M.D. (The author's profits on this book will be devoted to the Junius S. Morgau Benevolent Fund.) London: "The Hospital," Limited, 145 Strand, W. C., 1891. All rights reserved. Pages 131.

This is the history of the National Pension Fund for Nurses, as its second title denotes. The fund may be said to have had its origin in the misfortunes of a nurse of the Seaman's Hospital at Greenwich, who had a severe attack of typhoid fever after attending a typhoid patient. She became a permanent invalid in consequence, but the hospital authorities had no funds available for her continued support, and she had no resource but the work-house. Her case produced a deep impression upon Mr. Henry C. Burdett, who was at the time Secretary-Superintendent to the hospital and he determined to inaugurate some sort of a mutual assurance association which should provide a weekly sick benefit and a disability pension for trained nurses. He finally, after several years, and with the assistance of various philanthropic individuals, was enabled to see his pet scheme realized. The object of the history is to popularize and extend the benefits of the fund, and to increase its capital by donations and bequests. The history is interesting and the fund is

worthy of imitation in other countries, but the obstacles in the way of success are evidently such as would make failure easy for most men.

*Pocket Medical Dictionary, for the Use of Students of Medicine.* By CHARLES GATCHELL, M.D., Professor in the University of Michigan. Chicago: The Era Publishing Company. 1891.

This book contains ten thousand words, with a short definition of each. In no case is the meaning of a word described at length, which accounts for the possibility of including the large number of words in three hundred small pages. No attempt is made to go into the derivation of words, and where a word may be spelled in two ways, generally but one is given. In some cases the double vowel is retained, especially æ, and in others abandoned, especially e for æ. As a ready reference book for students or the practitioner it will be found useful, as it is compact and concise.

*Progressive Exercises in Practical Chemistry.* By HENRY LEFFMANN, M.D., Ph.D., and WILLIAM BEAM, M.A. Illustrated. Philadelphia: P. Blakiston, Son & Co. 1890.

This book includes the methods of laboratory instruction in inorganic chemistry given in the Woman's Medical College and in the Pennsylvania College of Dental Surgery. It is good enough of its kind, and we find nothing in it to criticise. Books of this kind are unquestionably useful to the authors and their students; but we do not believe they are of any value outside the schools in which they originate.

*A Guide to the Practical Examination of Urine.* By JAMES TYSON, M.D., Professor of Clinical Medicine in the University of Pennsylvania. Seventh Edition. Philadelphia: P. Blakiston, Son & Co. 1891.

This book is too well and favorably known to require any extended notice of this edition, which does not differ essentially from the one which preceded it. We believe the author would add somewhat to the value of his work by enlarging the chapter on diagnosis. Otherwise we have no suggestion or criticisms to make. The book is a reliable one, and should find a place in the library of every practitioner and student of medicine.

*Practical Notes on Urinary Analysis.* By WILLIAM B. CANFIELD, A.M., M.D., Lecturer on Clinical Medicine, University of Maryland, etc. Detroit: George S. Davis. 1891.

This is an addition to an already too long list of small works on the urine, and is fair specimen of a class which is rapidly becoming larger. It is in some respects tolerably good; but there are two or three works in urinary analysis which are very much better, and we do not believe there is any demand for this one.

*Post-Mortems: What to Look for, and How to Make them.* NEWTH and OWEN. Detroit, Michigan: Illustrated Medical Journal Comp.

A small compendium of information on pathological anatomy, intended, as the preface states, to serve as a "reminder to the busy practitioner."

It is little more than a catalogue of the changes found in the organs, with a short account of the method of performing an autopsy. It is not full enough to be of aid to any but a skilled pathologist, and he would have no need for such a book.

THE BOSTON

## Medical and Surgical Journal.

THURSDAY, NOVEMBER 5, 1891.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DANIEL L. UPHAM,  
283 WASHINGTON STREET, BOSTON, MASS.

## PSEUDO-TUBERCULOSIS.

IMMEDIATELY after Villemin's announcement, somewhat more than twenty years ago, of the specificity of tubercle, experiments were made (by Lebert and Wyss, by Cohnheim and Fränkel) which seemed to overthrow Villemin's conclusion as to the essentially infectious nature of tubercle. Morbid productions closely resembling tubercle were engendered in certain tissues by the implantation of foreign materials (cayenne pepper, cantharides, lycopodium, oyster shells, bits of putrid muscle) and even by the injection of pus (Roger). These experimental pseudo-tuberculosis products were afterwards studied by H. Martin, and by Cohnheim and other of the physiologists who were first deceived by their striking similarity to true tubercle.

Martin describes three varieties: with cantharides there are produced nodules formed by embryonal cells; with lycopodium the lesion is characterized by giant cells surrounded by round elements, while capsicum gives rise to true follicles constituted by the three classic zones which are observed in tuberculosis. Histology was incapable of differentiating these diverse granulations, but experimentation solved the problem by showing the absence of infectious properties in the tubercles engendered by the foreign substances; when inoculated in animals they failed to produce any tuberculous lesions, while true tubercle is inoculable in series and transmissible indefinitely from one animal to another.

Pseudo-tubercle by animal parasites have also been noted — little, yellowish, pale granules in the centre of which were found microscopic stronglyli, isolated or grouped in balls. These verminous tubercles have not as yet been seen in man, though frequently observed in the cat and in other animals. Koch has described a verminous pneumonia peculiar to the sheep, and due to the *pseudolius ovis pulmonalis*. These neoplasms are packed with round cells, and often contain one or more giant cells in their interior.

In 1883, after the announcement of Koch's discovery, and when the unity of tuberculosis seemed established,

Malassez and Vignal described a kind of tuberculosis proceeding from another parasite. On inoculating a cutaneous tubercle, they brought about a disease which was transmissible in series, and seemed to be produced by masses of zoogloea. Later on, in continuing their researches, they saw these animals succumb to bacillary lesions. They conclude (and their conclusion is supported by other observers as Charrin and Roger) that there exists a tuberculosis without Koch's bacillus, characterized by the presence of micrococci and short rods grouped in zoogloëic masses, and that the latter play in the organism which they infect, the rôle of irritant foreign bodies; the resulting tuberculosis they call *zoogloëic tuberculosis*. The appearance of Koch's bacillus late in the series of inoculations, they regard as accidental, that is, the bacillus tuberculosis was accidentally introduced.

Lastly, certain vegetal productions of an organization relatively high may cause the development of granulations more or less like those of tuberculosis, as has been shown in the recent treatise of Roger.<sup>1</sup> Thus, Pflüg has described in the cow, a tuberculous disease produced by the *actinomyces*; Nocard has shown that the disease improperly called *ox-farcy* is a pseudo-tuberculosis due to a parasite akin to *cladotrix*. Eppinger has observed in a man, granulations produced by a *cladotrix*, the *cladotrix asteroides*; the parasite has been cultivated, and its inoculation has reproduced in animals a milary tuberculosis.

Roger states that different varieties of *aspergillus*, and in particular the *aspergillus glaucus* and *fumigatus* may produce in animals, granulations with giant cells, in the centre of which is found the parasite, whose radiatory aspect resembles that of actinomyces.

Chaumesse and Vidal have observed in pigeons a milary pseudo-tuberculosis which was due to the *aspergillus fumigatus*, and which they have been able to reproduce by inoculating cultures of this vegetal. In individuals who exercise the profession of pigeon-feeders there are often observed respiratory troubles which seem to be due to the same parasite, as is inferred from the presence of the *aspergillus* in their sputa. Potain has published a case of like kind, and thinks that the *aspergillus* was acquired from the raw grain which the pigeon stuffers were in the habit of moistening in their mouths before feeding the pigeons with it. The affection seems to have a more favorable course than true tuberculosis.

## A STUDY OF THE TOXIC PRODUCTS IN THE URINE OF TYPHOID FEVER PATIENTS.

The elimination by the urine of the toxic products during typhoid fever, under different forms of treatment, has been investigated by two hospital physicians of Lyons, Drs. Roque and Weill, and is the theme of a contribution to the September issue of the *Revue de Médecine*, where their methods and conclusions are detailed. Weary of the advocacy of different treatments by the repetition of statistics, these investiga-

<sup>1</sup> Traité de Médecine, t. I, p. 668.

tors sought, by a study of the toxic products in the urine, to bring a more scientific element to bear upon the solution of the problems at issue.

They first endeavored to establish the "urotoxic coefficient" of typhoid fever without treatment, then that of typhoid under the cold bath treatment, and that of typhoid under an antipyretic treatment with antipyrine. Without reproducing their methods of analyzing the toxic products in the urine, or the details of the results of their estimates, we pass at once to the summing up of their conclusions, which are to the following effect:

In typhoid fever left to itself, the toxic products of the bacillus and of the organism are eliminated in part during the course of the disease; the "urotoxic coefficient" is double that of the "normal coefficient"; but the elimination is incomplete during the disease, and is prolonged into the convalescence, during five or six weeks of which it persists after the cessation of the febrile process.

In typhoid fever treated by cold baths, the elimination of the toxic products is enormous during the progress of the disease, the "urotoxic coefficient" being five or six times greater than normal. This hypertoxicity, however, diminishes as the general symptoms abate and as the temperature declines, to such an extent that, with the arrival of apyrexia and the beginning of convalescence, the exaggerated elimination of toxics is finished and the coefficient becomes normal again.

In typhoid fever treated by antipyrine, the elimination of toxic products is diminished during the disease to such an extent that the coefficient falls even below the normal. But with the arrival of convalescence the discharge of toxics suddenly begins in large amounts and lasts from five to seven days.

By a subsequent study, of the same kind, of typhoid under treatment by naphthol, Teissier finds that this drug acts as an antiseptic and prevents the formation of toxics, either during the disease or the convalescence.

Roque and Weill conclude that the cold bath is an eliminative treatment, it is in no sense specific, does not check the production of toxics, but secures their expulsion as fast as produced. Antipyrine (and the same should be true of the other coal-tar products) is not an antiseptic, it does not prevent the formation of toxic substances but prevents their elimination by the urine.

According to the conclusions of these authors the ideal treatment of typhoid fever with our present resources should be by naphthol internally and by cold baths externally. If these conclusions are correct, the practice of this combined treatment should result in some surprisingly favorable "statistics."

THE EMPRESS Frederick has recently opened a small model hospital at Cronburg, in the Taunus. It is to be maintained entirely at her own expense.

## MEDICAL NOTES.

NEW YORK PASTEUR INSTITUTE. — Dr. Paul Gibier, Director of the New York Pasteur Institute, gives the following results of the preventive inoculations against hydrophobia performed at this Institute during the first six months of the second year of its existence, February 18, 1891, to August 18, 1891. During this time 415 persons having been bitten by dogs, cats and other animals, applied for treatment. These patients may be divided in two categories: (1) In the case of 345 of these persons it was demonstrated that the animals attacking them were not mad. Consequently, the patients were sent back after having had their wounds attended to during the proper length of time. (2) In 70 cases the anti-hydrophobic treatment was applied, hydrophobia of the animals inflicting bites having been evidenced clinically, or by inoculation at the laboratory, and in many cases by the death of some other persons or animals bitten by the same dogs. Indigents have been treated free of charge. One death only, by hydrophobia, out of the 255 cases treated at this Institute is recorded, that of Miram Adams, five years old, of South Framingham, Mass. She was badly bitten July 14th last, in nineteen places by a dog, recognized to be mad. Treated from July 15th to August 1st. Symptoms of hydrophobia appeared six days later (August 6th). Died August 9th. Three other persons (two, sisters of the patient, and a man) bitten by the same dog, and who received the same course of treatment, are now enjoying good health.

SIRUPUS.—The last German Pharmacopœia changed the spelling of the work *syrupus* to *sirupus*, thus putting an official stamp upon the latter spelling, which had been recommended or used previously by various writers.

THE EMPEROR AND PROFESSOR HELMHOLTZ. — On the anniversary of the birthday of his father, Emperor William sent a congratulatory telegram to Professor von Helmholtz, at the same time conferring upon him the title "Wirklicher Geheimer Rath" and "Excellency." In the telegram the emperor says, "Your whole life has been given to the service of humanity, for whose benefit you have made a great number of glorious discoveries. Your mind, always directed to the purest and highest ideals, in its high flight left politics and party strife far behind. I and my people are proud to call so distinguished a man ours. I have chosen the birthday of my dearly-beloved and never-forgotten father for this mark of appreciation, knowing well how highly he valued you, and how devoted a friend and subject you were to him. May God long preserve your life for the good of Germany and the entire world." The sentence in which the emperor praises Helmholtz for having kept aloof from politics is being much commented on, and is certainly not without a meaning of its own, coming as it does just after the Virchow festivities, and considering the fact that no title was bestowed upon Virchow on the

occasion of his seventieth birthday, as had been expected by many of his friends.

#### NEW ENGLAND.

**MASSACHUSETTS MEDICAL BENEVOLENT SOCIETY.** — At the annual meeting held October 29th, the following officers were elected for the ensuing year: President, Dr. Henry W. Williams; Vice-President, Dr. R. M. Hodges; Treasurer, Dr. William L. Richardson; Secretary, Dr. Robert Amory; Trustees, Drs. D. W. Cheever, C. M. Green, C. H. Cook, G. E. Francis, R. C. Greenleaf, W. S. Bigelow, B. E. Cotting, Francis Minot, A. H. Johnson.

The treasurer reported that the invested funds of the Society now amount to about \$32,000; and that the income of the Society's funds and the annual assessments of the members of the Society had been distributed among thirteen beneficiaries, either physicians or members of deceased physicians' families. Dr. Francis Minot, who has been treasurer of the Society since 1857, declined re-election.

**MASSACHUSETTS CHARITABLE EYE AND EAR INFIRMARY.** — At the annual meeting last week, the secretary reported that the whole number of new patients during the year was 16,504, of which number 11,926 were eye patients and 4,517 ear patients. The whole number of house patients was 864. Of these, 742 were eye patients and 122 ear patients. Clement K. Fay was elected to the Board of Managers, in place of Dr. C. G. Weld, and the other members of the Board were re-elected as follows: Augustus Lowell, Edward I. Browne, Roger Wolcott, Augustus Hemenway, Arthur Rotch, Charles P. Curtis, Nathaniel Thayer, Percival Lowell, Harcourt Amory, Dr. J. Collins Warren, and George P. Gardner. Augustus Hemenway was re-elected treasurer, and Edward I. Browne, secretary.

#### NEW YORK.

**NEW YORK STATE MEDICAL ASSOCIATION.** — The eighth annual meeting of the Association was held at Mott Memorial Hall, on October 28, 29 and 30. The address of the President, Dr. Stephen Smith, was on "The Art of Teaching Medicine," and in it he deprecated to some extent the methods at present in vogue. "Questioning," he said, "is the basis of true teaching, and in every line of teaching this is followed except in teaching medicine. Clinical lectures do not meet the requirements. Medicine has reached the rank of a practical science, and should be taught under the immediate supervision of a competent instructor; and as the student advances in knowledge he should be advanced until graduation. The teacher should not be a morose preceptor, but a friend and companion of the student." Dr. Abram Dubois, who died during the past summer, left his valuable medical library to the State Medical Association.

**ST. JOHN'S GUILD.** — The twenty-sixth annual meeting of the Directors of the Guild was held October 27th, and the President, Mr. Wm. H. Wiley, in his address stated that in the twenty-five years' existence of the Guild, 156,135 sick children and their

mothers had been cared for on the floating hospital and at the seaside hospital on Staten Island.

**ROYAL PENSION FUND FOR NURSES.** — In the Chapel of St. Luke's Hospital, Mr. Henry C. Burdett, of London, recently explained the workings of the Royal National Pension Fund for Nurses, and a committee, among whose members are J. Pierpont Morgan, Cornelius Vanderbilt, and Dr. John S. Billings, of Washington, was appointed to devise a plan for organizing a similar fund in this country.

**DEATH FROM HYDROPHOBIA AFTER PREVENTIVE INOCULATION.** — Robert Morton, of Columbia, South Carolina, who was very severely bitten about the arms and hands by a rabid dog in August, and who was afterwards given a course of treatment at the New York Pasteur Institute, died of hydrophobia in October.

**SMALL-POX ON THE CANADIAN BORDER.** — The State Board of Health has notified all the health officers in the State along the Canadian border to exercise the utmost vigilance to prevent the spread of small-pox, as recent reports show that the disease is quite prevalent in Montreal and the province of Quebec. Up to the present time no cases has been reported in the State of New York.

### Miscellany.

#### THE GEORGIA BILL TO PREVENT DRUNKENNESS AMONG PHYSICIANS.

This bill, which has recently been extensively commented upon, has been vetoed by the governor, who gives the following reasons:

"I regret very much not to be able to give my sanction to any measure that might be considered as a protection to any part of the people against the evil effects of intemperance. I am unable, however, to approve this bill, for the following reasons: The bill provides that no physician or prescription clerk shall be allowed to practice medicine or fill a prescription who may become drunk from the use of either intoxicating liquor or opiates, while he or they are offering his or their professional services to the public, or in actual service. So much of the act has my hearty concurrence, and had it made provision for preventing such persons from practising medicine and filling prescriptions of medicine, which might have been accomplished through the medium of requirements of registration to practice medicine or license to fill prescriptions or some other appropriate method, I should have promptly given it my approval. But this bill in the second section provides that for a violation of the first section, that is, a physician who may become drunk while offering his professional services to the public, or in actual service, or a prescription clerk in a drug establishment who may become drunk while offering his services to the public, or in actual service as such prescription clerk, shall be guilty of a misdemeanor, and, on conviction, be fined. In this policy of legislation I cannot concur. Drunkenness on the part of practising physicians and prescription clerks is reprehensible, and

ought to be suppressed; but if it is a crime for them to be intoxicated, it ought to be a crime for others who get in like condition; and if it is no crime for others, it ought not to be a crime for them. It is the fact of drunkenness that would be punished if this act were a law, and not the acts arising from that condition; and if drunkenness is the gravamen of the offense all persons should come under the same law. If not all, then none."

#### A FURTHER COMMUNICATION CONCERNING TUBERCULIN.

IN a paper under this title Koch describes a method for separating a precipitate from tuberculin, which possesses the therapeutical properties of the cruder product, and which may, the author says, be the actual active principle.<sup>1</sup> After experimenting with several reagents he at last found that tuberculin containing sixty per cent. alcohol threw down a white flocculent precipitate, which could be washed and dried. This precipitate represents about one per cent. of the original tuberculin. Stronger solutions of alcohol throw down more, but at the same time bring down impurities which cannot be separated. As the therapeutic dose of the precipitate obtained by sixty per cent. alcohol is about one-fiftieth that of tuberculin, it may be considered as representing about one-half of the active principle of the crude product from which it was obtained.

The precipitate is moderately soluble in water, but deteriorates in aqueous solution, but in a fifty per cent. glycerine solution keeps perfectly well. Chemically, it shows all albumin reactions.

Both in animals and man the diagnostic and therapeutic action of the purified tuberculin is exactly the same as the original crude product, except that the dose, which for guinea-pigs is one-fiftieth, appears for man to be only one-fortieth. In conclusion, Koch says that although the purification of tuberculin has thrown no new light on its therapeutic value, he has not yet abandoned the study of its practical application.

At the end of his paper the author describes more in detail than he has formerly done, the process of preparing pure cultures of the tubercle bacillus, for the manufacture of tuberculin.

#### THE AREA AND POPULATION OF THE GLOBE.

THE recent publication of the *Bevölkerung der Erde*, of Drs. Wagner and Supan, by Perthes, of Gotha, gives us the most reliable information as to the area and population of the earth now obtainable.<sup>2</sup> The estimate for the total population of the earth in this present year is 1,480 millions, or an increase of 46 millions over the estimate for 1882, when the last edition of these statistics was published. The exact enumeration of 836 millions (about 56 per cent. of the whole population of the globe) has now been accomplished by census or registration. The population of the chief divisions of the globe is, in round numbers: in Europe, 357 millions, giving 94 inhabitants to each square mile of area; Asia, 825 millions, or 47 to the square mile; Africa, 163 millions, or 14 to the mile;

America, 121 millions, or 8 to the mile; Australia, 3 millions, or 1 to the mile; and in the Oceanic Islands, 7 millions, or 10 to the mile. In Europe, Belgium exceeds all other countries in density of population, with 530 persons to a square mile; next follows Holland, with 365; and the United Kingdom, with 312; but whereas in England the density is 480, in Scotland it is only about one-fourth, and in Ireland about one-third that of England. In Norway and Finland, the most thinly populated countries of Europe, there are only about 16 persons to the square mile. Of China the estimate is 361 millions, giving a density of about 77 to the square mile. It is in respect of Africa that the greatest doubt necessarily exists. The statistics make it manifest that there are still vast areas of the habitable surface of the earth almost, if not quite, unpeopled; and which will for many a long year to come receive the surplus millions of Europe and other parts of the globe in which the density of population is most keenly felt.

#### GONORRHOEA IN THE FEMALE.

BURN<sup>1</sup> from a long study of this subject concludes that gonorrhoea in women is a process limited to the superficial layer of the mucosa; the cocci invade the epithelial layer, but are always arrested when they reach the submucosa. The epithelium is originally cast off by reason of the active supuration, but is quickly renewed, assuming the pavement form; after this change has occurred the active invasion of gonococci is usually arrested, but they continue to grow in the secretion, in which they may persist for months and years. The gonococci have no connection with septic processes; they do indeed cause supuration of the mucosa, but are destroyed when they reach the subjacent connective tissue. If sepsis develops it must be in consequence of mixed infection; septic germs are frequently present in gonorrhoeal pus, and a favorable nidus for the reception of external germs is offered by the purulent genital secretion. The urethra and cervical canal are the favorite seats of gonorrhoeal infection; acute gonorrhoea of the cervix gives rise to symptoms only at the outset, but after it has become chronic it may exist for years without causing disturbances, unless it extends to the corpus uteri and thence to the tubes.

The cocci possess no power of spontaneous movement and extend only short distances by proliferation. Extension over larger surfaces must be through the agency of the secretion. Normally the cervical secretion cannot pass the os internum, which also serves as a barrier to the entrance of the specific infection. Menstruation favors the admission of cocci into the uterine cavity, also certain mechanical causes, such as coitus, the introduction of sounds and intra-uterine medication; lastly, this is liable to occur during the puerperium. After they have reached the cavity they again remain stationary, and probably are only carried into the tubes from the causes already mentioned, the puerperium being the most favorable time, as the proximal openings of the tubes are then more patent. In fifty-three patients with gonorrhoea, who were kept under observation for at least five months after the initial symptoms developed, the cervix was infected in 75 per cent., the corpus uteri in 15 per cent., and the tubes in only 3.5 per cent.

## THE POISON OF THE TOAD.

IN two letters which appeared in the *Lancet* of August 29th, a large amount of evidence is brought forward to show that Shakespeare's description of a toad "sweating venom," instead of being an expression of a mistaken popular idea, is really a truthful description of fact.<sup>1</sup> The toad secretes a venom of a tolerably powerful character: and instead of this secretion taking place, as in the case of snakes, entirely through glands in the mouth it is secreted by the skin. In his interesting letter, Dr. Leonard Guthrie mentions that the secretion also occurs in the toad through the parotid glands, and that the venom is a thick milky fluid like the juice of dandelion stalks in taste and appearance. When inoculated subcutaneously it kills small birds in six minutes, and dogs and guinea-pigs in half an hour to an hour and a half; the symptoms in birds being loss of coördination followed by death, in guinea-pigs convulsions, and in the dog depression, vomiting, and intoxication. Dr. Guthrie kept a small toad in a cage with some common lizards, and one day a lizard, having bitten the toad, immediately afterwards rushed wildly round the cage, burrowing its head in the sand, became convulsed, and died in less than two minutes. His dog having seized a toad, was attacked by instantaneous and profuse salivation, violent vomiting, and collapse. He also noticed that the venom has a most powerful local action on the skin, so that after carrying a toad in his hand he got numbness and tingling in it, with slight swelling and dryness of the skin lasting for several hours. In another letter Dr. Lauder Brunton mentions that the active principle of the toad venom is probably of an alkaloidal nature. It has been called phrynin or bufidin. It appears to be a cardiac poison, acting in somewhat the same way as digitalis; but its effects appear to resemble still more those of erythrophileum, for the uncertain gait, convulsions, and paralysis which it produces are precisely the symptoms produced by the erythrophileum when used as an ordeal poison. Dr. Guthrie's observation of the local action of toad's venom in causing numbness and tingling is interesting, as showing that in its local anæsthetic action phrynin resembles erythrophileum and digitalis, adds evidence to the generalization made by Dr. Lauder Brunton that all the drugs belonging to the group of so called cardiac poisons may have a local anæsthetic action.

## THE RESULTS OF VEGETARIAN DIET.

A RECENT number of the *Medical and Surgical Reporter* contains a translation of a letter by Dr. Alauus, giving his reasons for abandoning vegetarianism. He says,

"Having lived for a long time as a vegetarian without feeling any better or worse than formerly with mixed food, I made one day the disagreeable discovery that my arteries began to show signs of atheromatous degeneration. Particularly in the temporal and radial arteries this morbid process was unmistakable. Being still under forty, I could not interpret this symptom as a manifestation of old age, and being, furthermore, not addicted to drink, I was utterly unable to explain the matter. I turned it over and over in my mind without finding a solution of the enigma. I, however,

found the explanation quite accidentally in a work of that excellent physician, Dr. E. Mouin, of Paris. The following is the verbal translation of the passage in question: 'In order to continue the criticism of vegetarianism we must not ignore the work of the late lamented Gubler on the influence of a vegetable diet on the chalky degeneration of the arteries. Vegetable food, richer in mineral salts than that of animal origin, introduces more mineral salts into the blood. Raymond has observed numerous cases of atheroma in a monastery of vegetarian friars, amongst others that of the prior, a man scarcely thirty-two years old, whose arteries were already considerably indurated. The naval surgeon, Treille, has seen numerous cases of atheromatous degeneration in Bombay and Calcutta, where many people live exclusively on rice. A vegetable diet, therefore, ruins the blood-vessels and makes prematurely old, if it is true that man is as old as his arteries. It must produce at the same time tartar, the senile arch of the cornea, and phosphaturia.' Having unfortunately seen these newest results of medical investigation confirmed by my own case, I have, as a matter of course, returned to a mixed diet. I can no longer consider purely vegetable food as the normal diet of man, but only as a curative method, which is of the greatest service in various morbid states. Some patients may follow this diet for weeks and months, but it is not adapted for everybody's continued use. It is the same as with the starvation cure, which cures some patients, but is not fit to be used continually by the healthy. I have become richer by one experience, which has shown me that a single brutal fact can knock down the most beautiful theoretical structure."

THE DEPOPULATION OF FRANCE.<sup>1</sup>

THE discussions in the Académie de Médecine upon the causes and remedies for the stationary or diminishing character of the French population, as well as upon the leading questions of public sanitation, disease-prevention, and the loss of life due to the peculiar methods of infant farming, recently ended in the adoption of the following resolutions. This body rarely makes recommendations to the law-making power unsuccessfully, and it may be confidently expected that these measures will shortly take effect.

(1) That in each department there be established an asylum or refuge for the reception and care of women in the later months of pregnancy and in their accouchement. That, if so desired, absolute secrecy be observed. That there be an office to give succor and aid to persons unable to procure proper care for themselves and infants.

(2) That the law of December 23, 1874, for the protection of infants, be revised in some of its provisions, and notably that relating to "l'élevage mercenaire," in order that infants may not henceforth be left without the supervision and care of the parents.

(3) That vaccination and revaccination be made obligatory.

(4) As this law is of national importance (it has been recently adopted), the Academy recommends that vaccination and revaccination be encouraged and facilitated by all possible means at all times, and notably so when departments are advised of the appearance of

<sup>1</sup> *Lancet*, September 19th.

<sup>2</sup> C. A. Slegfried, in the *Nation*, October 15th.

indications of variola by the State Council of Hygiene, because, contrary to popular prejudice, vaccination and revaccination are the surest means of arresting the spread of small-pox and stamping it out of existence.

(5) That all school-children be vaccinated and revaccinated, as all soldiers and sailors are.

(6) That a vaccination service be organized throughout the country, without charge to the people, a day being fixed upon for the operation, which is to be performed as seems necessary.

(7) That small pox cases be isolated in all instances, in hospitals and elsewhere.

(8) That municipalities, prefects, and the powers that exist in communes be given sufficient authority by law to correct at once all insanitary conditions, and particularly to procure the supply of pure water without the admixture of sewage and surface contaminations.

The Academy has three times in the last ten years voted in favor of obligatory vaccination and revaccination. Many other public-health questions were under discussion, particularly measures looking to the prevention of typhoid and the commonly prevalent infectious diseases, the number of lives that could thus be saved annually aggregating, it is estimated, upwards of 150,000; but the above measures were the principal ones formulated and urgently pressed upon the attention of the French Parliament.

### THERAPEUTIC NOTES.

**THE EFFECT OF SALICYLIC ACID UPON THE VIRILE POWER.**—Corput<sup>1</sup> has noticed a diminution in the virile power of patients to whom he has given different antiseptics, such as quinine, menthol, carbolic acid, but especially salicylic acid. The spermatozoa lose their activity. Salicylic acid has a similar effect on the ovary, and prolongs the menstrual period.

**NEW METHOD FOR THE PRODUCTION OF PURE CHLOROFORM.**<sup>2</sup>—Dr. Raoul Pictet, who in the year 1877 converted oxygen and hydrogen into liquids by means of extreme cold and great pressure, has patented a new process invented by him, "for the purification of chloroform in cold." This process is based on the fact that on the reduction of temperature, the purest commercial chloroform at  $-70^{\circ}$  deposits a crystalline substance which is separated from the portion remaining liquid. The latter is then subjected to a temperature below  $-100^{\circ}$ , whereupon the chloroform itself separates in the form of crystals, and may be removed from the contaminating portion which remains liquid. The chloroform thus purified possesses at  $15^{\circ}$  a specific gravity of 1.51, and is not modified by the influence of daylight. By virtue of this purification, the chloroform becomes capable of indefinite storing without the addition of alcohol. On shaking with concentrated sulphuric acid, coloration of the latter does not occur, even after a considerable time. Solution of dichromate of potash and sulphuric acid, on shaking with this chloroform remains yellow, whilst heretofore the purest commercial brands of chloroform exercised a reducing action on the mixture—noticeable by the appearance of a greenish coloration. Hopes have been expressed by several operators that chloroform thus pre-

pared will be safer as an anæsthetic than the less pure drug.

**IODOFORM IN TUBERCULOSIS.**—Flick regards its curative powers as being limited to those cases in which the circulation has not yet been cut off from the deposit.<sup>3</sup> It is dissolved in cod liver or olive oil, and is given by injection; the preparation should last for several weeks.

**ANTIPYRIN ON THE SECRETION OF MILK.**—Ginbert<sup>4</sup> has found antipyrin of use in arresting the secretion of milk. It should not be given unless the kidneys are normal. He gives four grains every two hours, and generally obtains the desired result in two days.

**ERGOTIN.**—For subcutaneous use Biedert recommends the following solution.<sup>5</sup> The preparation keeps well, and is not irritating.

R Ergotin . . . . . gr. xv.  
Aque destil . . . . . gr. lxxv.  
Acidi carbolici . . . . . gr. ʒ.

FOR ECZEMA, not of a chronic nature.<sup>6</sup>

R Thymol . . . . . 2 grammes.  
Oxide of zinc } . . . . . ʒi 25 grammes.  
Starch . . . . . ʒi 25 grammes.  
Lano in . . . . . 50 grammes.  
M. Bat unguentum. Sig., salve, to be applied to the affected parts.

**ACETANILID IN THE TREATMENT OF ACUTE AND CHRONIC BRONCHITIS.**—In an account of some original observations, Grün describes what he believes to be the specific bacillus of acute bronchitis.<sup>7</sup> This bacillus is about twice as long as it is broad, and appears to give off spores. It stains with gentian violet and methyl blue, and occurs in the pus cells, free, and on the particles of epithelium. It can be grown on agar-agar and nutritive gelatine. The addition of iodoform, creasote and several other well-known antiseptics did not prevent its growth in the cultures. Acetanilid added to the cultures invariably prevented its growth. He then cites twenty-five cases of acute bronchitis and one of chronic bronchitis, in which the administration of five grains of acetanilid every other hour caused disappearance of all symptoms in about twenty-four hours. He asks a trial of the remedy in such cases.

Peabody	10,158	1	0	—	—	—	—	—

Deaths reported 3,072: under five years of age 1,296; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 603, consumption 333, acute lung diseases 257, diarrhoeal diseases 241, diphtheria and croup 171, typhoid fever 103, whooping-cough 29, scarlet fever 23, cerebro-spinal meningitis 14, malarial fever 13, measles 10, erysipelas 2.

From whooping-cough Chicago 6, New York, Baltimore, Pittsburgh and Washington 3 each, Philadelphia and Nashville 2 each, Cincinnati, Charleston, Fall River and Fitchburg 1 each. From scarlet fever Chicago 11, New York 5, Philadelphia 7, Brooklyn and Baltimore 4 each, Cincinnati 2. From cerebro-spinal meningitis Chicago 4, Washington 3, Brooklyn 2, Boston, Worcester, Lynn and New Bedford 1 each. From malarial fever Brooklyn 6, New York 4, Nashville 2. From measles New York 10.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,105,108, for the week ending October 10th, the death-rate was 18.4. Deaths reported 3,312: diarrhoea 233, whooping-cough 73, fever 54, measles 39, diphtheria 55, scarlet fever 25, small-pox (Birmingham) 4.

The death-rates ranged from 12.2 in Brighton to 25.8 in Sunderland, Birmingham 17.8, Bradford 15.9, Hull 24.3, Leeds 18.5, Leicester 15.1, Liverpool 23.0, London 17.2, Manchester 23.3, Newcastle-on-Tyne 24.2, Preston 23.7, Sheffield 16.5.

In Edinburgh 15.7, Glasgow 23.3, Dublin 23.0.

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 24, 1891, TO OCTOBER 31, 1891.

FIRST LIEUTENANT ROBERT R. BALL, assistant surgeon, U. S. A., granted leave of absence for one month, with permission to apply for an extension of one month.

CAPTAIN LOUIS M. MAIR, assistant surgeon, U. S. A., relieved from duty at Whipple Baracks, Ariz., and ordered to Fort Apache, Ariz., for duty.

CAPTAIN CHARLES F. HARRIS, assistant surgeon, U. S. A., is relieved from duty at Fort Logan, Col., and will report in person to the commandant of the Military Prison, Fort Leavenworth, Kan., for duty.

CAPTAIN VICTOR BIART, assistant surgeon, U. S. A., having been found incapacitated for active service, on account of disability incident to the service, is, by direction of the President, retired from active service, to date October 21, 1891.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING OCTOBER 31, 1891.

HENRY P. HARVEY, surgeon, ordered to Receiving-ship "St. Louis."

JAMES M. FLINT, surgeon, detached from Smithsonian Institution, and to the U. S. S. "Miantonomah."

T. C. HEYL, surgeon, detached from Receiving-ship "St. Louis," and wait orders.

## OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING OCTOBER 24, 1891.

PURVIANCE, GEORGE, surgeon. Upon completion of duties as chairman of Examining Board to inspect marine hospitals at St. Louis, Mo., Cairo, Ill., and Cincinnati, O. October 16, 1891.

GODFREY, JOHN, surgeon. To represent the Service at the meeting of the American Public Health Association. October 14, 1891. To inspect Marine Hospital at Louisville, Ky. October 14, 1891.

CARTER, H. R., passed assistant surgeon. Granted leave of absence for thirty days. October 17, 1891.

PETTUS, W. J., passed assistant surgeon. Orders to Norfolk, Va., revoked, to proceed to Cape Charles Quarantine for temporary duty. October 14, 1891.

KINYOUN, J. J., passed assistant surgeon. To represent the Service at the meeting of the American Public Health Association. October 17, 1891.

PERRY, T. B., passed assistant surgeon. To proceed to Norfolk, Va., for temporary duty. October 14, 1891.

GUTTERAS, G. M., assistant surgeon. To proceed to Gulf Quarantine for duty. October 20, 1891.

ROSENAU, M. J., assistant surgeon. Granted leave of absence for thirty days. October 24, 1891.

## SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A regular meeting of the Society will be held on Monday, November 9, 1891, at the Medical Library, 19 Boylston Place, at 8 o'clock p. m.

Drs. Philip C. Knapp and Abner Post, "Two Cases of Trephining for Traumatic Epilepsy." Dr. James J. Putnam, "The Nature and Causes of Traumatic Epilepsy, with Special Reference to Treatment." G. G. SEARS, M.D., Secretary.

## BOOKS AND PAMPHLETS RECEIVED.

Transactions of the United States Medical Practitioners' Protective Alliance. New York, 1891.

Mechanical Massage. By E. D. Eastman, M.D., Superintendent of State Insane Asylum, Topeka, Kan. 1891.

The Physicians Ready Reference Account Book. Arranged by Gideon C. Segur, M.D. Hartford, Conn.: The Plimpton Manufacturing Co.

Epidemic Influenza, Notes on its Origin and Method of Spread. By Richard Sisley, M.D., M.R.C.P., Lond. London and New York: Longmans, Green & Co. 1891.

CLINICAL ASPECTS AND ETIOLOGICAL RELATIONS OF CUTANEOUS TUBERCULOSIS.<sup>1</sup>

BY JAMES C. WHITE, M.D.,

Professor of Dermatology in Harvard University.

THERE is no disease within the special province of this Association which so much demands its earnest consideration as this, which has been selected for formal discussion to-day; for not only is tuberculosis of the vital tissues one of the most fatal and widespread destroyers of man, and in its cutaneous forms the source of frightful disfigurement, but great confusion exists with regard to the nature and mutual relations of some of its manifestations. The diversity of opinion which exists in the profession throughout the civilized world upon this point, has been made prominently manifest in the innumerable discussions and reports upon the action of Koch's remedy, which have been published during the past year. Such a universal and synchronous census of prevalent professional views upon any subject in medical pathology is unparalleled in history. If this cyclonic experimentation in therapeutics, fanned into a popular craze by the public press, and conducted to a lamentable and almost ridiculous end by the over-enthusiasm of its medical supporters, who in many instances knew as little of the external phases of the disease they were treating as they did of the remedy they were employing, shall result in no more immediate good than the creation of a proper interest in the study of the manifold manifestations of cutaneous tuberculosis, it will not have vexed the world in vain.

It is my function, as I interpret the instructions of the Council, to place the subject in its clinical and etiological relations before you in as simple a form as possible for discussion. Before this body it will be unnecessary more than briefly to indicate those well-recognized conditions of the skin, which have been hitherto assigned a more or less individual or independent position in cutaneous pathology among dermatologists, and which, with certain other less clearly defined conditions, it will be my object to show, are only progressive phases or clinical forms of a single affection.

## I. — LUPUS VULGARIS.

I may be pardoned if I attempt to define before you the meaning of this term, as ordinarily used, by the briefest sketch of the lesions which characterize its course. The vast and needless number of specific terms which have been invented to express each particular phase of development or involution and every clinical form, shows the great diversity of these manifestations. Several distinct types of its primary stages are recognized. The formation of apparent macules varying in size from a point to a pea, or larger areas of irregular outline, neither of which are elevated above the general surface, but are felt to represent infiltrations of the cutaneous tissues of varying depths — *L. maculosus, planus*. Papules, tubercles, nodules, or much larger areas elevated above the surrounding skin to the extent of a line to a half-inch. Like the former lesions these are found to extend more or less deeply into the skin, and exhibit the same boggy, yielding consistence when pressed upon with any blunt pointed

instrument. These constitute *L. tuberculosis, nodosus, elevatus, tumidus, non-exedens, non-ulcerosus*. A more minute description of these ordinary early lesions, included under the common term lupoma, would be wholly superfluous.

Some modifications of these forms occur through progressive changes in the surrounding cutaneous tissues. Thus we may have an accompanying lymphangitis, persistent oedema, teleangiectasis, great general thickening or pachydermia, with papillary hypertrophy of the affected regions, *L. adenomatosus, hypertrophicus, papillosus, elephaniticus*, etc.

All these cutaneous changes constitute the various manifestations in its periods of progressive development or evolution.

Lupus undergoes involution or retrogression by interstitial resorption, fibrous degeneration, and ulceration. The earliest indication of the first named process is a change in the epidermal covering of the primary lesions in the form of scales in varying amount, *L. exfoliatus, psoriasis*. Then follow a shrinking and depression of the elevations, and the slow formation of a smooth scar, an atrophic process. The fibrous forms of metamorphosis are divided by Vidal and Leloir into a so-called *L. sclereux*, which is never total, and is regarded by them as a slowly progressive form of development which remains virulent, containing bacilli and yielding positive results on inoculation, and *L. sclerosus, fibrosus*, a retrogressive change, no longer virulent, and not to be confounded with the scar formation which follows ulcerative forms.

Ulceration takes place in lupus tissue in a variety of forms, *L. exedens, ulcerosus*, which, according to the rapidity or penetration of the process, has received other designations — *superficialis, serpiginosus, profundus, vorax, phagadenicus*. The determining causes of this secondary process are not clearly understood. It is most probably not the result of the action of the tubercle bacillus, but of the accidental introduction into tissues already impressed by the former of suppuration-producing cocci.

The outcome of this destructive process is the eventual formation of true cicatricial tissue, and the development during its course of a variety of transitory conditions: crusting stages are *L. crustosus, rupoides*; excessive or exuberant granulation is *L. fungoides, vegetans*. Finally, the cicatrix is established, capable itself further of hypertrophy, *L. keloides*, and of presenting every possible appearance in its permanent state, according to the seat, treatment, etc.

These are the cutaneous changes which constitute the conditions ordinarily comprised under the term lupus. With so many elements of expression at command, it is evident that with its chronic course and associated dermatoses of occasional occurrence, dermatitis, erysipelas, etc., it is capable of exhibiting very great variety of appearances in individual cases.

II. — TUBERCULOSIS VERRUCOSA,  
VERRUCA NECROGENICA.

*Verruca necrogenica*, or anatomical tubercle, had long been recognized as a chronic, inflammatory, wart-like tubercle, affecting primarily the fingers of persons working in dissecting and autopsy rooms, ward-tenders, and butchers. In the last revision of our system of classification, in 1884, it was placed under "hypertrophies of the epidermal and papillary layers," next to

<sup>1</sup> Read at the meeting of the American Dermatological Association at Washington, September 23, 1891, introductory to the discussion upon Cutaneous Tuberculosis.

ordinary verruca. Besnier and Vidal were the first to call attention to its occurrence upon persons making autopsies of subjects dying of consumption, and its resemblance to some forms of lupus. In 1884, bacilli were discovered in its tissues. In 1885 they were also found in several instances in the tubercles which had probably been produced by tuberculous inoculation, and in the inflamed axillary glands connected therewith. Early in 1886, Riehl and Paltauf published their article on "*Tuberculosis Verrucosa Cutis*," in which the clinical and anatomical features of this now well-recognized form were described, and its probable identity with the more restricted anatomical tubercle established. The presence of the tubercle bacillus in the lesions of all clinical varieties was also demonstrated. Since then its peculiar and multiform features have become familiar to dermatologists everywhere, as its occurrence is found to be by no means rare, and but few fail to regard it as a phase of cutaneous tuberculosis. It may fairly, I think, be accepted as the ordinary form of manifestation in the cutaneous tissues of the inoculation of the same with tuberculous matter, whether derived from the cadaver of man or other animal, or by contact with infective material from living subjects. There is a considerable variation in the character of the lesions, from the primary and small nodule of more or less inflammatory type with its subsequent wart-like papillary hypertrophy, to the more extensive areas of deeper infiltration and greater prominence, characterized by well-marked verrucous transformations of some parts of its surface, by isolated or grouped, dull or purplish-red tubercles or nodules in others, and by depressed cicatricial changes in the central or other portions. Areas thus affected may be an inch, or even several inches in diameter, and may present various combinations of the above lesions. The papillomatous features may be wholly absent. When the plaques are multiple, and this condition is by no means infrequent upon the hands, we have opportunity of seeing how varied may be the expression of the disease even upon the same individual. The amount of inflammation incident to the developmental stages is variable also, manifesting itself in zones of surrounding dermatitis, or in the formation of superficial or deeper foci of suppuration within the diseased tissues. It rarely undergoes ulceration. But I need not more particularly describe a condition with which you are all familiar, and concerning which several members of this Association have recently published communications. Among them Dr. Morrow's case is especially noteworthy, as occurring upon the face and presenting so exceptional a form of papillomatous lesion.

### III. — TUBERCULOSIS CUTIS.

This title was applied, before its true and more comprehensive significance had become so generally accepted by dermatologists, to certain rare forms of disease, which must be here mentioned. In nearly all text-books and general treatises on skin diseases, even those most recently published, one finds the same definition, a brief transcript in fact of the description of certain ulcers observed by Jarsch, Chiari, Kaposi, and others, occurring about the orifices of patients in advanced stages of consumption, upon the lips, about the anus and vulva, and extending to the adjoining mucous membrane. These ulcers were discreet and shallow, had eroded, slightly infiltrated, irregular edges, and presented a reddish-yellow, granulating

surface. Miliary tubercles were found associated with their extension within the buccal cavity, and in one instance within the true cutaneous tissues surrounding the ulcer. There is no apparent reason for regarding these classic cases as otherwise than exceptional forms of local auto-inoculation, assuming a rapidly ulcerative state from the generally depraved condition of the patients' tissues. There is certainly nothing in them to warrant the establishment of a special class on their account.

Under the title *dermatitis tuberculosa acuta*, or general miliary tuberculosis, Heller has described the case of a child in which there was an outbreak of macules, papules, vesicles, and bullæ over the whole surface, subsequent to the development of caseous glands adherent to the right innominate vein. Bacilli were found in the contents of the vesicles, and in sections of the affected tissues.

Under the term *tuberculosis pustulo-ulcerose* Dr. Gaucher, of Paris, described at the last meeting of the International Congress of Dermatology an affection occurring in young children, characterized by impetiginous pustules, superficial in their early stage, but terminating in deep ulcerations, circular in shape, and covered with crusts. Inoculation of the pus from these lesions upon animals produced mild peritoneal tuberculosis. He regarded it as identical with some of the cases described by older writers as *impetigo rodens*. The process was of benignant type.

### IV. — SCROFULODERMA.

This is a term most commonly applied to the progressive changes which take place in the skin covering so-called scrofulous glands in the neck. The primary seat of the process is generally either in the subcutaneous fibrous tissue, in the lymph glands themselves, or in the periglandular structures. Briefly described there is first noticed a firm, circumscribed infiltration beneath the skin, which slowly becomes larger and more prominent, and finally is felt to soften. The overlying skin is sooner or later implicated, becomes hyperemic, thinner, and finally breaks down at one or several points, allowing the escape of the fluid matters beneath. Thus is established an ulcer. These ulcers vary greatly in appearance, size, numbers and duration, and heal after months or years, by the formation of variable scars. The process in its various phases has received the following names: scrofulous glands, scrofulous sores, white swelling, cold abscess, *gommes scrofuluses*, *gommes scrofulo-tuberculeuses*. Similar chronic changes resulting in destruction often take place in the skin overlying tuberculous disease of joints and bones.

Here, too, must be placed tuberculous dactylitis, a condition of the fingers and toes, principally the former, in young children, characterized by bottle-shaped enlargement and chronic inflammation of the overlying integument, and terminating often in destructive ulceration of the same. This affection is of much more common occurrence than the syphilitic process, which it so closely resembles, and is, in my opinion, often mistaken for the latter. The ulceration resulting from all these forms, but especially that connected with scrofulous glands in the cervical region, sometimes extends far beyond the original underlying disease into the surrounding integument, and may continue to progress indefinitely, destroying large areas of skin, or new foci of ulceration may establish them-

selves in the neighborhood of the primary ulcer by the process of auto-inoculation without doubt.

Closely allied to these ordinary forms of glandular tuberculosis is a rare affection described by Hallopeau and Goupil under the title *Lymphangiectasie suppurative tuberculeuse*. Swellings form along the course of the lymphatics, varying in size from a filbert to a small egg. The overlying skin softens and ulcerates, and gives issue to a discharge of lymph containing bacilli. The process upon the lower legs is accompanied by much swelling.

Certain dermatoses have been regarded by writers as forms of scrofuloderma, as the so-called lichen scrofulosum. They are disorders of the skin occurring at times in patients who are affected by tuberculosis, but they are in no way tuberculous processes.

Perhaps some reference should here be made to Unna's "tuberculous eczema," so-called. That the skin immediately surrounding tuberculous lesions in an active state may be stimulated into a sympathetic dermatitis of eczematous type is well known, and that an eczema in a person affected with tuberculosis of any tissue of sufficient gravity to impair general vitality may be somewhat modified by such an impression is not improbable, but I have seen no reason advanced for recognizing a specific tuberculous eczema. Such an appellation without proof is as objectionable to me as the expression "syphilitic eczema."

Finally, in connection with such pseudo-tuberculosis, I desire to state that in my opinion there is not sufficient evidence for regarding lupus erythematosus as an affection to be considered in this paper.

There are some other forms of disease of the integument, tuberculous in character, which are occasionally met with, closely allied to some of the clinical forms above described, which, I have reason to believe, are not ordinarily recognized as such, and which I have been in the habit of designating as unclassified tuberculosis. With the simple statement that they are mostly deep-seated, chronic processes of restricted area and often associated with evidences of tuberculosis elsewhere, I will not attempt to define them more particularly now. This is equivalent to the statement of my opinion that we are not yet thoroughly familiar with all possible manifestations of cutaneous tuberculosis.

Such then are the tissue changes by which tuberculosis manifests itself in the cutaneous structures. The mere enumeration of the processes shows how varied are the methods by which the skin expresses its resentment of the irritating presence of the virus. We find that we may have erythema, followed by deep infiltrations of corresponding size and hyperæmic elevations, ranging from small papules to tubercles of large size, which may gradually undergo absorption and leave atrophied scars, or soften and remain in conditions of discharge and open ulceration indefinitely, destroying by serpiginous progress large extents of integument, and terminating in depressed or hypertrophied scars. Firm and densely sclerous infiltrations without marked tumidity and verrucous outgrowth, not tending to secondary changes. Forms of flattened papilloma-like hypertrophy of extremely slow development. Ulceration and destruction of the skin overlying glands primarily affected; deep and prominent, circumscribed nodular infiltrations often of considerable size (gummata), leading to destructive softening and ulcers of indolent type. Tumidity and breaking down of the integument

covering phalanges, and primary affections of the larger bones and joints as well. In the surrounding areas of skin not immediately affected we may have dermatitis of various grades and kinds, as well as the implication of subcutaneous structures in the process, the glands, lymph vessels, fibrous tissues, cartilage and bones.

The particular nature of the minute anatomical changes which give rise to these varied appearances, it is not my province to speak of; this will be presented to your consideration by our more competent colleague, Dr. Bowen.

By the concurrence of certain of these lesions in various arrangements and combinations, differing somewhat in sequence, course and duration, in the locality affected and clinical history, more or less well-marked groups have come to be recognized as forming independent affections. It would be needless to look backwards and endeavor to discover a satisfactory reason as to why these ever varying types of one disease have been so long kept apart and regarded as distinct affections. Loose observation, narrow views of pathology, respect for the dicta of the older teachers, antagonism of schools have prevented us from recognizing and properly interpreting the identity of the anatomical and clinical features common to all these pseudo-independent phases. We see the same disposition to unduly magnify the importance and individuality of distinct clinical forms in the two great kindred diseases, syphilis and leprosy, until recently. Sharply marked dividing lines have been supposed to separate the former into well defined stages to the confusion of the student and practitioner, and the equally artificial division between the so called anaesthetic and tubercular forms of the latter has largely delayed the recognition of its essential etiological nature. The true method of determining the mutual relations of the various diseased conditions we are discussing is by close observation of the features common to them all, and their points of approach and convergence (to coin a word) in individual cases, and not by confining our efforts to demonstrating how far apart certain selected clinical types apparently stand. Let us consider, then, what evidence we possess to-day, unbiased by previously formed opinions, so far as possible, of their clinical and etiological unity.

I. The concurrence of various clinical forms in the same individual.

Since my attention has been especially directed with in the last few years to the question of the probable tuberculous character of various obscure conditions of the skin, which I had previously and hastily regarded as chronic inflammatory processes, warty hypertrophies, ulcers of uncertain origin, scrofulous sores, bone disease, questionable syphilitic lesions, or other undetermined cutaneous changes, which make up that too large residuum in the classification of cases in hospital clinics, often bunched under the title, "uncertain diagnosis," and my understanding of their real nature has been made clear to me, I have been surprised to note the frequency of association of various clinical forms in the same person. Perhaps I cannot better illustrate such concurrence than by placing together the notes of cases bearing upon this point, which have fallen under my observation in the past three years.

(1) Girl, aged seventeen. Enlarged glands in neck in state of ulceration; extensive ulceration of surrounding skin; patch of serpiginous lupus on upper right thigh.

(2) Girl, aged eighteen. Chronic ulcerating glands in neck; chronic tubercles on leg in state of ulceration; ulcer on palate; lately, tubercular lupus of nose.

(3) Man, aged thirty. Serpiginous lupus of face, of varied type, said to have begun after a cut upon its site. Fifteen years' duration. Lately, a patch of deep tubercular infiltration upon arm.

(4) Girl, aged sixteen. Swollen glands in neck for eight years. Lately, active ulceration extending in broad belt from ear to ear.

(5) Girl, aged twenty. Scrofulous glands in neck, some of them in state of ulceration. Tubercular and ulcerative lupus on front neck. Sclerous lupus of face. Solitary and large tubercle on back.

(6) Child, aged eight. Verrucous tuberculosis of wrist. Lupus-like tubercles on knee and arm.

(7) Child, eighteen months old. Tuberculous dactylitis of fingers. Chronic scattered tubercles on same arm.

(8) Child, aged nine months. Dactylitis of one hand. Scattered nodules and tubercles on arms and legs.

(9) Child, aged six. Swollen glands in neck, surrounded by large areas of cutaneous ulceration; exuberant ulcerative lupus of nose.

(10) Man, aged sixty-three. Multiple tuberculosis verrucosa of fingers of left hand. On same forearm tubercular, ulcerative and fibrous lupus occupying a large area.

Some of these cases offer striking illustrations as well of the concurrence of such cutaneous forms with pulmonary or deep joint tuberculosis, but I shall ask your attention to such association later. They will recall, I doubt not, many similar cases within the recent observation of all of you, and are numerous enough to establish the fact of the frequency of such mixed manifestations in the same person. The very frequent connection of lupus proper with the so-called scrofulous state, is well known. I need only refer to the familiar statistics of Raudnitz and Pontoppidan, recently collected. The former found evidence of scrofulosis in thirty per cent. of 209 cases of lupus, and the latter determined a scrofulous basis in a still larger percentage in lupus.

Several objections would be raised, I am aware, by the opponents of these modern views of unification to evidence drawn from facts as these just presented. First, that the simultaneous or consecutive occurrence of such forms is mere coincidence, or that lupus is associated with scrofuloderma, because they are both indications of a depraved vitality, although independent affections. This is, of course, simply a restatement of the old dictum, the very proofless assumption which so long remained unquestioned. Second, that the cutaneous lesions exhibited in my cases, with the exception of the "scrofulous" glandular disease, disposed of as above stated, were merely the protean manifestations of lupus alone. But this would be extending the definition of lupus to an extent so comprehensive as to include every form of cutaneous tuberculosis, or, in other words, to admit the unity we are contending for. Third, it may be asked, How do you know that the extraordinary lesions described by you as associated with your lupus and scrofuloderma cases are tuberculous in their nature, admitting for the moment that the latter changes are so? Because in many examples of all these forms this fact has been established by careful examination of their anatomical and

bacterial elements, and by inoculation experiments conducted by many competent observers. It may be also legitimately replied, How does one know that unusual forms of cutaneous lesions occurring in an analogous affection are positively syphilodermata? Does one challenge the syphilographer to establish such diagnosis by microscope and inoculation? No, one must trust the skilled observation of the accomplished dermatologist to recognize the nature and position of many changes in the cutaneous tissues by shades of difference in appearances so minute that they cannot be expressed in words.

II. The presence of the *bacillus tuberculosis* in all clinical forms.

The data on which this all-important proof of the essential identity of these conditions rests are now so numerous, have been gathered by so reliable observers in all parts of the world, and are on record in so many well-known publications, that it will only be necessary for my purpose to present them in as succinct a shape as possible.

(1) *Lupus*. In the active and developmental stages of every lesion recognized as characteristic of lupus vulgaris bacilli occur. They are found inside and outside of cells, often in the tissues surrounding the lesion, are always sparsely distributed, and are of low vitality compared with the activity they manifest in other forms of tuberculosis. In the retrogressive phases they are still less abundant, or cannot with our present tests be discovered at all.

(2) *Tuberculosis verrucosa*. The bacillus has been found in every active stage of every clinical variety of this form also.

(3) *Tuberculosis cutis*. In the various forms of disease above described under this head, including the general acute military affection and a variety of ulcerative processes, bacilli have been found, in the fluids of vesicular and pustular lesions, and in the secretions of ulcers.

(4) *Scrofuloderma*. In every form of cutaneous scrofulosis the bacilli also occur. In the glands in their active and caseous stages of inflammation, in the discharges from the overlying skin, when implicated in the process, and in the ulceration of the integument spreading from such foci or excited in surrounding areas through probable auto-inoculation. They were discovered also by Hallopeau in the suppurative lymphangiectasis described by him.

There are few dermatologists now, I presume, who doubt the occurrence of this bacillus in every form of cutaneous tuberculosis, or who misjudge the negative significance of its relative sparseness and inactive qualities in these various clinical phases. That this bacillus is the direct exciting cause of all the lesions we have been considering, there can be, I think, as little remaining doubt. The gross character of these cutaneous manifestations, their course, and their very diversity of type is in close analogy with that of other great bacillus disease, leprosy, as with syphilis, whose kindred nature, I doubt not, will ere long be as positively demonstrated. It is of little moment to discuss whether the bacillus produces this manifold impression upon the cutaneous tissues containing it by its mere mechanical presence, or by the irritative action of ptomaines or other chemical agents produced by it, the responsibility rests upon the tangible bacterium. That this bacillus in all these forms is the same, and that it is identical with that of pulmonary tuberculosis is proved by the results of

### III. Inoculation Experiments.

Here, too, it would be wholly a waste of time for me to present to you the details of the experimentation so extensively conducted in all parts of the world since the introduction of this test by Professor Koch. It has established the following facts:

The bacilli of pulmonary tuberculosis when inoculated upon guinea-pigs produces tuberculosis. Pure and prolonged cultures of the same produce like results.

The cutaneous tissues of scrofuloderma, lupus, anatomical tubercle, tuberculosis verrucosa, and miliary tuberculosis have all repeatedly produced more or less general tuberculosis when inoculated upon this animal.

According to Lingard the intensity or virulence of the effects of such inoculation varies in accordance with the activity of the bacillus growth in these respective forms. Thus guinea-pigs inoculated with the tubercular matter found in sputa or verrucous tuberculosis, die of tuberculosis on an average in 80 days, inoculated with material from scrofulous glands in 206 days, and with lupus tissue in 331 days. These results are confirmed by Leloir's investigations. He regards the difference between lupus and other forms of tuberculosis, so far as their comparative virulence is concerned, to be one of quantity rather than of quality.

Now the natural conclusion from these experiments is that these materials, derived from such various clinical forms of disease, produce one and the same form of tuberculosis in animals, because they are all merely varying expressions of the same disease. An objection has been raised, as you know, to the soundness of such conclusions on the ground that these inoculations should reproduce the respective local forms from which the material employed was derived; that is, that lupus inoculated should produce lupus. Setting aside the reports of the few cases in which such local lesions have resulted as might be thus interpreted as too exceptional to establish such a possibility, it seems to me a perfectly satisfactory explanation, that the cutaneous tissues of the animals experimented upon are simply an unfavorable soil for the development of the bacillus tuberculosis. Is it not as difficult to inoculate leprosy upon animals (or syphilis) and does not the bacillus of leprosy show a strong selective affinity for certain human tissues over others? The inoculation of material from syphilitic lesions upon human tissues does not reproduce the form of lesion or stage of the disease from which it was derived. Why then should this be expected of the lesion or stage of tuberculosis hitherto called lupus? We know too little of the conditions which influence the biology of bacilli to permit such arguments to control legitimate deduction from the positive data furnished by these experiments.

IV. Auto-inoculation. Transference of infection from one host to another.

But opportunities are not wanting of studying the effects of the inoculation of many or all these forms of tuberculosis upon the human skin, although this has not been conducted by design or studied in the initial stages. Instances of the transference of the disease from one part of the cutaneous surface to another, or from one host to another, are so numerous that this origin of skin tuberculosis cannot be denied. The history of the sequence of development of many a case of multiple forms, of which examples from my clinic have been already cited, warrant this conclusion.

The details need not be repeated. Cronier reports cases in which lupus was developed after spontaneous openings of caseous lymph glands, collections of pus in bones, and deep fistulas. Five were cases of gland origin, three of osteomyelitis. Achard cites numerous cases of lupus verrucosus occurring on the seats of former subcutaneous gummata. Such secondary forms can immediately follow the evacuation of matter, or after long periods, if the discharge become chronic.

When we consider how exceptionally restricted is the seat of lupus generally, how extremely slow in its ordinary course to invade even its peripheral tissues, confining itself to a small and single area for twenty, fifty or even more years, it seems to me that the consecutive invasions of new territory, often widely separated from each other, can be most reasonably explained in the majority of cases on the theory of re- or auto-inoculation. We find in accordance with this view that multiple seats of lupus forms occur most frequently in children, in whom the disease is more active and open than in adults, whose cutaneous tissues are no doubt more susceptible of infection than those of the latter, and with whom transference of infectious materials from one part of the surface to another is so likely to occur from habits of picking sores, from the more frequent nudity of portions of the integument, and from the more restless contact of the hands with all parts of the body. Cases have been frequently reported where lupus has developed primarily upon the seat of wounds. We shall see below, other evidence of successful direct inoculation of tuberculous matter.

A study of the clinical history of cases shows, too, that cutaneous tuberculosis may be transferred from one person to another, without necessarily repeating the form from which it was derived. The following are cases observed by myself:

Child, aged eight. Verrucous tuberculosis of wrist. Scattered tubercles on knee and arm. A younger sister has similar tubercles on one arm of later development.

Girl, aged seventeen. Verrucous lesions and open ulcerating forms upon both feet. Serpiginous crusting lupus on one thigh. Duration of process three years. Has lived in closest intimacy with a sister who presents extensive areas of multiform tuberculosis of the skin of many years' duration.

I might refer to other instances of lupus occurring in more than one member of the same family within my experience, but these are under present observation. They are not of so frequent occurrence as to indicate that cutaneous tuberculosis is readily or often transferred from one host to another, and this is in accordance with our knowledge of the comparative inactivity or low vitality, and sparse development of the bacillus in these forms.

On the other hand, there is an extensive collection of observations, which demonstrate how readily the skin may become infected by bacilli in the more active condition and greater abundance in which they occur in the sputa of pulmonary tuberculosis. Jadassohn reports a case of the development of lupus upon the site of a tattoo mark, coinciding with the lines of the design. The operator had pthiasis, and mixed his pigments with his own saliva. Dubreuilh has collected seventeen cases of tuberculosis of the penis after circumcision, in which the ritual operator was in consumption. The peculiar nature of this operation

is well known to you all. In several of these bacilli were found in the lesions. Behrend gives an account of a patient with laryngeal and pulmonary phthisis, who was bitten by a guat on the finger, produced an excoriation of the part by scratching, and wetted it repeatedly with saliva. This terminated in a sore, which did not heal, and presented every appearance of cutaneous tuberculosis. In Dubreuilh's case a young woman washed the handkerchiefs containing the sputa of a phthisical patient. Nodules developed upon her fingers, followed by swelling and suppuration of the axillary glands. In the next few weeks small nodules appeared along the course of the arm, which broke down and discharged. The original lesions upon the hands became verrucous. Bacilli were found in all the lesions and in the discharge from the axilla. Inoculation in guinea-pigs gave positive results.

Here follow the cases of cutaneous tuberculosis which have occurred under my own observation within the last three years, in which favorable conditions for such infection through sputa existed:

Woman, aged thirty-two. Chronic tubercular mass on thumb of two years' duration. For a long time previous to its appearance she had been nursing her husband in consumption.

Child, aged eighteen months. Scattered tubercular lesions on arm, with dactylitis of hand. Mother died of consumption after nursing it six months.

Child, aged nine months. Dactylitis and many scattered tubercles on limbs. Mother had phthisis.

Woman, aged sixty-five. Diffused infiltrated patch on back of hand, and verrucous lesion on finger of same. Was nursing daughter in consumption when it appeared.

Woman, aged sixty-six. Multiform lesions on back of left hand and forearm of six years' duration. It appeared while nursing daughter in consumption.

Child, aged twelve. Open ulcerative lupus of nose. Sclerous lupus on neck. Sister has ulcerative tuberculosis of palate.

Woman, aged fifty-eight. Verrucous tuberculosis of finger. It appeared two years ago, just after nursing daughter, who died of consumption.

Woman, aged forty-eight. Open ulcerative tuberculosis of left wrist of eighteen months' duration. Her husband and daughter have died of consumption within the last two years. The latter had "open sores."

Girl, aged six. Swollen glands in neck, surrounded by extensive ulceration for three years. Exuberant ulcerative lupus of nose of six months' duration. Father died of consumption when she was fourteen months old.

Man, aged sixty-three. Numerous tubercular and ulcerative lesions covering large areas upon the left forearm. Several deeply infiltrated verrucous forms on fingers of left hand. The disease began on finger seven years ago, about the time of the death of wife from consumption.

Woman, aged twenty-four. Tuberculosis verrucosa of left forefinger of five years' duration. Mother died of chronic consumption two years ago, and was nursed by her.

Woman, aged forty-eight. Verrucous tuberculosis of two fingers of nine months' duration. Had previously attended a patient in consumption, who had also died for four months an "open sore" on neck.

The cases of probable inoculation might be corroborated by great numbers of others taken from re-

cent reports. Dubreuilh, who has collected sixty of them, presents the following account of the usual course of the process: The earliest lesions after inoculation in an adult are generally either a panaris or an ulcer with a livid erythematous border, becoming later verrucous in portions or over its whole area. In the vicinity of the primary sore nodules, either within or beneath the cutaneous tissues, often appear along the course of the lymphatics, presenting at times the aspect of scrofulous gummata, and followed by adenitis. In infants tuberculous meningitis has often supervened, and in adults these local manifestations have frequently terminated in pulmonary tuberculosis. He concludes farther, that infective matter derived from surgical tubercle, which is poor in bacilli, produces a cutaneous tuberculosis of slow progress, lupus forms, which is also poor in bacilli, whereas the inoculation of tuberculous sputa gives rise to painful ulcerations and carious lesions rich in bacilli.

Now it may be claimed that all such cases as these by no means prove the fact of inoculation, but that they may be explained on the old theory of diathesis, which has hitherto given such complete and easy satisfaction. Everybody must admit that diathesis, so-called, is only an inferential condition, and rests on no scientific or tangible basis whatever, whereas inoculation with infective matter and consecutive tissue changes, both local and universal, is a fact capable of the clearest demonstration. If, then, we can explain a series of observed facts, which closely resemble in their successive details the undoubted phenomena produced, artificially or otherwise, by inoculation, why should we ever think of interpreting their occurrence on a purely imaginative basis of causation? Why should we resort to pure assumption or supposition until natural and physical methods of accounting for their occurrence are first shown to be of impossible application? The days of diathesis are numbered, I believe, and their figmentary existence will vanish when it is shown that they are no longer necessary to explain the occurrence of diseases which closer observation is demonstrating to be capable of interpretation under laws which come within the scope of scientific reasoning and experimentation. A diathesis will, in my opinion, ere long be shown to be as unnecessary for the explanation of all the phenomena of tuberculosis, as it is to-day for leprosy, and always has been for syphilis.

In every one of the cases I have reported from my own observation, the undoubted opportunity for inoculation was present. It is, of course, impossible to fix the precise date of this event in studying the history of a case at a period so remote from its inception, nor have we yet positive knowledge of the period of incubation, or sufficient data as to the appearances of the earliest local manifestations after inoculation. Such evidence as these family cases present would be accepted without the slightest hesitation as a satisfactory explanation of the source of syphilitic infection developing in wife, child, or nurse of a patient affected with this disease. Why then should we regard with more scepticism the lessons as to the contagiousness of tuberculosis which these cases teach? When we consider the possible opportunities of contact with the infectious sputa of consumption, which occur in families under the existing carelessness and ignorance concerning their dangerous character which everywhere prevails, it is only surprising that such cases are not more frequent. It can only be explained on the ground

that the cutaneous tissues of man are but slightly susceptible to the reception, and afford an infertile soil for the development of the bacillus tuberculosis. Leloir, in his recent communication to the *Congrès de la Tuberculose*, gave the results of his inoculation of lupus tissue upon animals in two hundred cases. He found that it never produced tuberculosis in the guinea-pig when inoculated into the hypoderm, but that it almost infallibly produced the disease when inoculated into the peritoneum of the same animal. It may be considered probable, indeed, that a sound epidermis is a complete shield of safety against the dangers of inoculation by surface contact. Would that the mucous membranes possessed the same immunity!

#### V. Association with pulmonary tuberculosis.

Another proof of the identity of these various forms of cutaneous disease with tuberculosis, is their by no means infrequent connection with the pulmonary form in the same person. I need only quote from well-known statistics to establish this significant concurrence: Besnier has reported that twenty-one per cent. of his lupus patients died of phthisis; Leloir states that of nineteen lupus cases ten were in consumption; Sachs reports that of 166 cases of lupus thirty-four per cent. had tuberculosis in some form before the cutaneous manifestations, and sixty-two per cent. subsequent to the development of the latter. Such ratios might be largely extended by quoting the figures of other observers. The following three cases from my clinic within the last year will serve as an illustration of such association of forms in America, an experience which would be corroborated by the observation of all who are present, I have no doubt.

Girl, aged sixteen. Lupus of nose of six years' duration. Unmistakable signs of tuberculosis of right upper lung.

Woman, aged forty. Tuberculosis of left thumb, and palm and back of right hand. In advanced chronic consumption.

Mau, aged thirty-five. Sclerous and ulcerative lupus of upper thorax. Apex of lung affected.

The secondary infection of the skin in pulmonary tuberculosis admits of ready explanation, for sputa rich in active bacilli must be constantly coming in contact with the fingers in the use of the handkerchief, and the hands are often used to wipe the mouth after expectoration or coughing among the poorer classes, as is well known. The prevalence of such uncleanly habits and the infrequency of such transfers, strongly illustrates, as just mentioned, the immunity of the skin to such chances.

The development of pulmonary tuberculosis subsequent to the existence of cutaneous forms upon an individual, may be explained, of course, by the direct transfer of infective matter from open lesions upon the surface to the air-passages, and such extension to internal organs in any way is in accordance with the clinical record of kindred diseases. The manifestations of syphilis may be confined wholly, or for a considerable period of its course, to the skin, whilst in leprosy it may long be the only field of exhibition before other tissues are affected.

I should not neglect in this connection to mention the opinion which prevails among French dermatologists, that pulmonary tuberculosis is often developed as a result of the operation of scarification, as used by them in the treatment of lupus, in consequence of thus setting free the bacilli to enter the general circulation.

In connection with this question of self-infection, it may be of interest to note that at the meeting of the *Congrès de la Tuberculose* just referred to, M. Lespinne described certain manifestations observed at times in cases of lupus, chiefly in ulcerative forms, which indicated a general intoxication of the system. They consisted of rapid elevation of temperature, catarrhal symptoms of the mucus and serous tissues, and a typhoidal condition, simulating a diphtheritis, or acute miliary granulation. As soon as the elimination of these infectious products has been accomplished, these phenomena disappear, or they may be the precursor of a more general tuberculosis. He has seen them terminate in this disease of the peritoneum and lungs. In his opinion this state of general infection could be caused either by the bacilli or the agents of suppuration in the lupus tissue.

With all this accumulation of varied evidence bearing upon the question, the concurrence of various forms upon the skin of the same person, the demonstration of one bacillus in all these clinical forms, the uniform results of the inoculation of such tissues and the bacterium itself upon animals, the clinical proofs of re- or auto-inoculations of these forms upon the original patient and of their transference to others, the established association with pulmonary forms of the disease, with all this evidence, I say, I do not see how any reasonable doubt can be entertained with regard to the essential identity of every form of tuberculosis with which we are acquainted.

#### RELATIVE FREQUENCY OF CUTANEOUS FORMS.

It has been common belief amongst us that lupus is far less prevalent in this country than in Europe, whilst pulmonary tuberculosis is of more frequent occurrence here than there. Of the correctness of the former opinion I have presented statistical proof to this Association in former communications.<sup>2</sup> Such unequal prevalence among nations may well be explained by the differences in habits of personal cleanliness which characterize them. But with the enlargement of our definition of lupus we have been considering, these figures need revision, and the inquiry should comprehend all forms of cutaneous tuberculosis. With regard to the comparative prevalence of these various clinical forms amongst ourselves, I can only present the following brief statistics gathered from my own observations during the last two years in my clinic at the Massachusetts General Hospital. In this period sixty-nine new cases of cutaneous tuberculosis were recorded, representing the following clinical varieties: Scrofuloderma, thirty-four; lupus vulgaris, five; other forms, thirty. This subdivision is not intended, of course, to represent sharply differentiated processes in all cases, but it loosely expresses with sufficient accuracy, the relative prevalence of the clinical varieties as they occur here. The ratio of their combined number to all cases of skin disease observed at my clinic during the same period is 69 to 4,644.

#### AGE.

It was the tenet of Professor Hebra that lupus rarely, if ever, developed after the age of twenty, and usually showed its first manifestations in childhood. This rule was often used to determine diagnosis in doubtful cases. It may be that typical lupus does

<sup>2</sup> Variations in Prevalence, etc., 1876. Immigrant Dermatoses, 1890.

present itself in the majority of instances at this early period of life, and, if so, it must be accounted for by the greater susceptibility of the skin in youth to the reception of the specific germ. We see confirmation of this in the character of the lesions and the greater activity of the process which lupus always exhibits at this age, and its not infrequent spontaneous and complete extinction after middle life. So far, however, as the history of the other clinical forms we have been considering, teaches, it is apparent from the case above cited within my observation, that no such limitation to the dangers of inoculation exists, and that the skin exhibits such susceptibility both in middle life and at advanced age.

#### HEREDITY.

Upon this important etiological question, I beg to reproduce here, the opinion I expressed in a paper on "Hereditary Dermatoses" communicated to the International Congress of Dermatology and Syphilology held at Paris, in 1889, and I do this with less hesitation because it has not been published in a form generally accessible to members of this Association.

That general or pulmonary tuberculosis is hereditary and transmissible has been commonly accepted as a perfectly settled fact, as it seemed to furnish the only plausible ground for its marked occurrence in families. It has never been denied, however, that it might develop independently of inheritance. When its bacillus nature was recognized, it furnished a satisfactory explanation of the occurrence of the latter class of cases. But it also raises the question, if it will not likewise account for cases hitherto regarded as hereditary, that is, for every case. Admitting the infectious character of tuberculosis in any form at all, and the capability of transference from person to person by direct contagion or inoculation, is the theory of hereditary longer necessary? *A priori* we cannot deny the possibility of intra-uterine infection, even if the connection between mother and fetus is so little directly intimate, nor of the preceding bacillous inoculation of ovulum or the male germ. Such cases of congenital infection are extremely rare. The burden of proof in this question should, it seems to me, as was said of leprosy, be transferred to the advocates of the hypothesis of heredity. As to the transmission of a predisposition which shall render a person more liable to the disease after birth, but which is not the disease and requires a fresh infection to make such peculiar fertility available, that is a nicety in the problem of heredity which I cannot appreciate, considering that the bacillus of every form of tuberculosis is readily received and developed in the normal tissues of perfectly healthy animals. So, too, with regard to some tissue changes of childhood regarded as the indirect result of tuberculosis and not tuberculosis itself.

Mr. Francis Galton, in his recent interesting work on "Natural Inheritance" gives the history of 66 marriages in which one of the parents had "consumption." There resulted from these unions 113 children, of which number 107 had, or were suspected to have, consumption, equal to twenty-six per cent. Inasmuch as its prevalence in the general population is sixteen per cent, his inference is that this increase in rate may be fairly attributed to the greater chances of infection in such families. He found, too, that when the mother was the consumptive parent, the proportion of consumptive children was larger than when

the father was the affected parent, which he explained by the fact that during infancy the child "lies for hours daily in its mother's arms, and afterwards lies much by her side, breathing the tainted air of her sheltered rooms." If the infant may acquire the disease from the milk of tuberculous cows, why not also from that of its diseased mother? We may not claim then that any case of cutaneous tuberculosis in any form is inherited until every possible source of extraterine infection has been eliminated.

#### CONCLUSIONS.

In conclusion, it seems to me, that on the evidence in our possession, collected within the last few years, under a more enlightened and unbiassed judgment as to its pathology, and presented in a necessarily brief and incomplete form in this paper, we are warranted to regard the various clinical conditions of the skin we have been considering, as simply cutaneous phases of one comprehensive affection, which, with its pulmonary and other tissue manifestations, constitute that most important of all diseases, tuberculosis; as much a unit as the equally multiform cutaneous lesions and other tissue changes which characterize syphilis and leprosy. In my opinion it would greatly conduce to the quicker adoption of this consistent view of the true relations of all its forms, if we should entirely cease to make use of such independent terms as lupus and scrofuloderma, and hereafter designate such clinical or local varieties by no more distinctive titles than we employ in the description of the manifestations of leprosy or syphilis. The sooner and clearer we make it apparent to the public and the profession that all lesions of tuberculosis are dangerous and contagious, and mutually convertible, the more easily shall we gain control over the future course of the greatest scourge of mankind.

#### THE PATHOLOGY OF CUTANEOUS TUBERCULOSIS.<sup>1</sup>

BY JOHN T. BOWEN, M.D.,

Physician for Diseases of the Skin, Carney Hospital; Assistant for Diseases of the Skin, Massachusetts General Hospital.

In this paper, that I have the honor to contribute to the discussion upon the subject of cutaneous tuberculosis, I shall confine myself as closely as possible to the anatomy of the various forms of this disease, considering that allied questions often discussed under the head of pathology, will be presented more properly by the other participants.

Under the head of cutaneous tuberculosis, we must include, in the present state of our knowledge, scrofuloderma, lupus, and two other clinical forms that were not until recently admitted to a place in this class. These two forms, the only ones, with the exception of lupus and scrofuloderma, that have offered substantial claim to be considered as distinct varieties, are the military tuberculosis and tuberculosis verrucosa cutis. We have thus four forms of cutaneous tuberculosis to consider, scrofuloderma, lupus, military tuberculosis and tuberculosis verrucosa cutis. The claims of tuberculosis verrucosa cutis to be regarded as a distinct variety have sometimes been questioned, and will be considered in their proper place.

No one doubts to-day that in tuberculosis we have

<sup>1</sup> Read at the meeting of the American Dermatological Association, in Washington, September 23, 1891, introductory to the discussion upon Cutaneous Tuberculosis.

to do with a chronic infectious disease caused by the action of a specific bacillus. The work of Koch and Baumgarten, together with the valuable contributions of other investigators, has demonstrated this truth so brilliantly and positively, that no other belief in the domain of pathology can be regarded as more securely established. Furthermore, the same investigators have cleared up the mystery surrounding the term *scrofula*, by demonstrating that the larger part at all events, of the affection formerly termed *scrofulous*, are in reality tuberculous troubles, caused by the tubercle bacillus. In proof of this, they have shown that this bacillus is constantly present and capable of culture in generations, and that these cultures when inoculated upon other organisms produce a true tuberculosis. The subject of lupus has also been vastly illuminated by the pathological studies that have followed in the wake of the discoveries of Koch. For a long time searched for in vain, it was finally proved by Koch, Doutelepout and others, that the bacillus of tuberculosis, although very sparingly represented, could be demonstrated by a prolonged search in sections of lupus tissue, and further experiment showed that it could be cultivated in generations, and produce tuberculosis by inoculation upon animals. The sole pathological proof that to the most skeptical could now be wanting, was the production of lupus itself by inoculation, and although the clinical evidence that lupus may sometimes at least be caused by a direct inoculation of sputum or other material rich in tuberculous virus, is increasing, it must be admitted that experiment has not as yet succeeded in producing this disease in animals. In consideration of the insusceptibility of the lower animals to many forms of human disease, it seems probable that the last doubt will have to be dispelled by an overwhelming accumulation of clinical facts. The anatomist may fairly demand the aid of the clinician, and an intelligent judgment can only be formed by a consideration of all the evidence.

The tubercle, the product of the tubercle bacillus, is a nodule of so-called granulation tissue, composed histologically of small, round cells deeply stained by coloring agents, together with larger cells possessing a clear nucleus, that have been called epithelioid cells, and large cellular elements, with peripherally arranged nuclei and homogeneous centre, the Langhans giant cells. These cells are enclosed between the meshes of connective tissue, and are characterized, in distinction from normal cells, by their instability. Sooner or later a modification begins in the nodule. Its centre becomes necrotic, that is, the cell protoplasm is coagulated, the nuclei lose their power of responding to staining agents, the intercellular substance also takes part in the degeneration, and there results a coagulation necrosis in the Weigert sense, a condition that has been usually termed a cheesy degeneration. This term, cheesy degeneration, has given rise to much confusion. Virchow long ago pointed out that it was in no sense a condition peculiar to tuberculosis. Its use should be restricted to the macroscopical appearance and consistency of certain products of degeneration, dropping the term entirely from the nomenclature of microscopy.

It has been claimed, at various periods in the history of tuberculosis, that both the cheesy degeneration and the Langhans giant cell were pathognomonic of the affection. Neither of them can now be considered as a specific attribute, inasmuch as cheesy degeneration

is found, as has been said, in numerous other conditions, and as the Langhans giant cell, while still retaining an especial association with tuberculosis, can frequently be seen in its typical form in the tissue about vessel ligatures, and in several forms of syphilis— notably in gummata and in the small papular or lichenoid variety. Baumgarten's view that those cases of syphilis in which the Langhans giant cell is found, are a complication of syphilis with tuberculosis, has not been supported by microscopical study nor by experiment. No one has claimed to have found the bacillus of tuberculosis in a gumma, or in a papule of lichen syphiliticus, and experiments upon animals have failed to produce tuberculosis by the inoculation of these syphilitic products. Still, while the Langhans giant cell has lost its claim to be regarded as specific, a certain amount of diagnostic value must be allowed to it, when seen, as there is as yet, so far as I am aware, no record of its discovery in pathological processes other than those of tuberculosis and syphilis.

While it may be said that the course and life history of the tubercle, together with its tendency to progress in the adjacent tissue are to some extent specific, the sole feature that we have practically to regard as pathognomonic, is the presence of the tubercle bacillus. The doctrine of to-day reads, every neoplasm that contains the bacillus of tuberculosis is tubercle, and in every tubercle the bacillus must be present, however, sparingly.

Great progress has of late been made in the histogenesis of tuberculosis, by the aid offered by the tubercle bacillus, and by the discovery of new methods of hardening and staining. These methods were inaugurated by Flemming in his search for the evidences of nuclear division, and have been constantly extended and improved. The belief that had existed for some time, under the influence of Cohnheim's exudation theory, that the epithelioid and giant cells of tubercle are produced from the emigrated white blood cells, has been essentially shattered by the experiments of Baumgarten.

Baumgarten introduced bits of tuberculous tissue into the anterior chamber of the eye of guinea-pigs, and allowed the infection to progress for varying lengths of time, when the animals were killed, and the tissue subjected to the modern methods for the detection of karyokinesis. On the second day there begins to be an increase in the number of bacilli, which spread into the neighboring tissue. The first signs of the new tubercle are epithelioid cells, which are seen to be produced from the fixed tissue cells by karyokinesis, and not from the leucocytes or small, round cells. Indeed, the leucocytes are not observed until a later period in the development of the tubercle, and no karyokinesis has been seen in them at any stage. Hence Baumgarten regards the epithelioid cells as derived from a proliferation of the fixed tissue cells, and not, as had been supposed, from the leucocytes. It has been doubted whether we are yet justified in regarding the epithelioid cells as in all instances derived from the fixed cells alone, and the history of tuberculosis, with its ever changing beliefs, may properly urge upon us caution in our positive assertions. Nevertheless, the experiments of Baumgarten have proved conclusively that the emigrated white blood cells bear a subordinate part in the development of the tubercle, and that the normal cells of the affected part are the first to be impressed by the virus, which

causes them to assume the epithelioid shape. Next occurs the infiltration of the tissue with leucocytes, which may be present in greater or lesser numbers. When the infiltration with leucocytes has reached its acme, there begins to be a degeneration and death of the cells forming the tubercle. The leucocytes are probably the first to degenerate, they refuse to become stained, and a molecular detritus results. The epithelioid cells are the next victims to the degeneration, their protoplasm begins to shrivel up, and a coagulation necrosis is produced. A further step in the degeneration is a softening of the necrotic mass, and the appearances of a suppuration are falsely produced. But there is no suppuration in tubercle strictly speaking. No pus cells are found with the microscope in pure tubercle, and there can only be a real suppuration when the tuberculosis is complicated with a septic process.

The histogenesis of the Langhans giant cells has been the subject of much controversy. The best belief of to-day is that they are formed not by confluence of several cells, but by nuclear proliferation of a single cell, with failure of the protoplasm to divide. According to Weigert's view, the Langhans cell represents a tubercle in miniature. The centre of the cell undergoes a partial coagulation necrosis, while a proliferation of the nuclei occurs faster than the cell body can divide, thus giving us the picture of a single cell with nuclei arranged along its edge, and a homogeneous centre of necrosis. The failure of the protoplasm to divide so fast as do the nuclei, is probably caused by the irritant not being powerful enough to carry the process of cell proliferation beyond its first stage, that of a division of the nucleus. The irritant in the case of tuberculosis is the tubercle bacillus, and if the bacilli are present in great numbers, the Langhans cell is not found, as the cell proliferation occurs so quickly that the cell division keeps pace with the nuclear division. This theory is strikingly supported by the case of lupus, where the bacilli are very sparingly present, and where for this reason the number of Langhans cells is very large—much larger than in acute military tuberculosis, for example, where the whole process is accelerated, and the bacilli are found in great numbers. Furthermore, the Langhans cells often contain bacilli, situated along the periphery, the part that still lives, and to which they turn for nourishment when the centre has become necrotic.

The theory of Metschnikoff with regard to the Langhans cells of tubercle should be mentioned, on account of the attention that it has excited, and of the ingenuity with which its originator has argued its claims. His theory is that the protection of the organism against many species of bacteria lies in the white blood corpuscles, which seek out the bacilli for their nutriment. The cells that thus receive and feed upon the bacteria, he has called phagocytes, and to this class the Langhans giant cells of tubercle belong. A struggle for existence is constantly taking place between the cells and the micro-organisms, and the bacilli when overwhelmed by their antagonists, are subjected to an intra-cellular digestion by which they are annihilated. Able supporters have rallied to Metschnikoff's aid in his phagocyte theory; but without entering further into the controversy that has arisen, it must be said that the active characteristics that the Langhans cell must possess in order to carry on its warfare with the tubercle bacilli, have not been satisfactorily proved,

and that the weight of authority is not in favor of this theory.

Turning now to the special features presented by cutaneous tuberculosis, the first form to consider is:

#### MILITARY TUBERCULOSIS OF THE SKIN,

as this is the form that represents almost exactly the tubercle of internal organs. It has been called by the French "*tuberculose ulcéreuse*," but as the property of ulceration is common to many forms of cutaneous tuberculosis, the better title is that of military tuberculosis, on account of the almost constant presence of military nodules in process of rapid necrobiosis. Clinically this form consists of painful ulcers situated at the juncture of the mucous membrane with the skin at the entrance to the mouth, nose, anus and vagina, and also upon the ear, in patients suffering from pronounced tuberculosis of internal organs. This form is also met with on the mucous membrane alone, and rarely attacks the skin except by extension outward from mucous surfaces. The edges of the ulcer are characteristic, being made up of a series of small indentations, looking as if punched out. Military tubercles in the form of yellowish-white transparent nodules can usually be seen in parts of the ulcer. The lesions are rapidly progressive, from a degeneration of the military tubercles, and from the confluence of the small ulcers. To Chiari and Jarisch are due the first accurate descriptions of this form, at a time when the tubercle bacillus had not been discovered. Chiari's observations prove the rarity of these ulcers for they were found in only five cases out of a total of 7,000 autopsies, sixty per cent. of the subjects of which were tuberculous.

These lesions have not, so far as my knowledge extends, been studied in the light of the modern histological methods. But all the pathological examinations that have been made, tend to prove the similarity of their structure to that of the military tuberculosis of internal organs. The cutis is found to be filled to a considerable depth with foci of small, round cells, with occasional epithelioid and Langhans giant cells. In the centre of these foci the necrosis has progressed rapidly, so that upon macroscopical examination the appearances of softening and cheesy degeneration are apparent. The tubercles often by their condition form masses of softened and necrotic tissue, in which the evidences of unaltered granulation tissue can only be found in the outlying parts.

In the number of bacilli found in this military form there is, I am convinced, a further analogy with the military tubercle of the internal organs. In the cases that I have examined they were present in large numbers, in one every field contained enormous masses, and this accords with the experience of Riehl, Doutrelepon and others.

This form has often been classed as a true tuberculosis of the skin, and offered as a powerful argument against the tuberculous nature of lupus, on the ground that the bacteriological and histological features of lupus differ in many respects from this military form. That this form presents characteristics not seen, as a rule, in lupus, is freely admitted, but the differences are just those that distinguish an acute from a more slowly progressive tuberculosis of other parts. The process in the military form runs a more rapid course. The cells are speedily transformed into masses of necrosis of a cheesy consistency, and the cause of this

accelerated degeneration lies in the great numbers of tubercle bacilli, — phenomena that have been shown to be the rule in acute military tuberculosis.

#### SCROFULODERMA.

The term scrofuloderma is used to describe those cases of tuberculosis where the subcutaneous tissue and the lower portions of the corium, are the seat of the morbid process. Very commonly the starting point is a lymph gland, in which the tuberculous material is formed under the influence of the bacilli, becomes necrotic, and finally breaks into the overlying tissues. Where several lymph glands are involved, deep ulcers with fistulæ of various lengths are often produced. The anatomical character of scrofuloderma differs in no essential way from the tuberculosis of internal organs. A granulation tissue of small round and epithelioid cells, with a moderate quantity of Langhans giant cells, has its seat in the subcutaneous tissue, becomes degenerated, and may break through the thinned and tense layers of the epidermis above, giving rise to the well-known ulcer with soft undermined edges. The degeneration is usually much farther advanced than in lupus, large areas of necrotic, softened tissue being usually visible under the microscope. Experiment by inoculation has, as has been said, proved beyond a doubt that these scrofulous glands and ulcers are a tuberculosis of the subcutaneous tissues. The specific tubercle bacilli are always present. Their detection may, in some instances, be a matter of considerable difficulty; in others they are very abundant, and in general they are much more numerous than is the case in lupus, but not so thickly sown as in the military form just considered.

#### LUPUS.

In lupus we have a tuberculous affection, having its starting point in the corium, affecting primarily the lower portions, progressing upward by extension of the foci of disease, and causing in most instances secondary and non-specific alterations of the epithelial elements. Before the discovery of the tubercle bacillus, histological investigation had already pointed out with much clearness the resemblance existing between the anatomical features of lupus and tuberculosis. Friedländer contributed more than all others to a correct appreciation of this similarity, and argued that the points of difference were not distinctly defined enough to separate the two affections. A considerable controversy then arose between the advocates and opponents of the identity of the two affections on anatomical grounds. Baumgarten pointed out that the cheesy degeneration, so constant in tubercle, was wanting in lupus; that lupus tissue presented less epithelioid and more giant cells; that lupus was more vascular, gave rise to a greater formation of connective tissue, did not present so sharply defined military nodules, and was capable of direct suppuration. For these anatomical reasons he considered that lupus should be separated distinctly from tuberculosis. These points of difference, that are true in the main, are now cited to prove the identity rather than the dissimilarity of the affections. Suppuration, however, cannot be claimed as an attribute of lupus, any more than of tuberculosis, as Neisser has pointed out, and as is now generally acknowledged. What we have been accustomed to call suppuration is in reality a breaking down and softening of the granulation tissue. A true suppuration often

occurs, but only when a septic process is engrafted on the tuberculous tissue. With regard to the other objections of Baumgarten, they are precisely the points of difference between a rapidly progressive and a more chronic and less virulent process. "Cheesy degeneration," the synonym for an advanced necrobiosis, is not seen in lupus, on account of its slow progress and the small number of bacilli that are present. Whether or not the soil is here unfavorable to their existence, as has been often suggested, they are found in much smaller numbers in cutaneous than in most other forms of tuberculosis. Military cutaneous tuberculosis offers the sole exception to this rule, as here the bacilli are usually found in great numbers, and therefore, as would be expected, the tissue presents anatomically a more advanced necrosis.

The larger representation of giant cells and the smaller number of epithelioid cells as seen in lupus, are also characteristics of the more slowly developing forms of tuberculosis, as has been shown by experimentation upon animals, by feeding them with attenuated cultures of tubercle bacilli. In these experiments a very slow and sparse proliferation of the bacilli takes place, and the neoplasm does not progress beyond the stage of the primary epithelioid cell tubercle, or to one verging upon the lymphoid cell tubercle — much the same appearances that we meet with in lupus.

The histogenesis of the Langhans cell has already been referred to in speaking of tuberculosis generally, and the increased numbers of these cells in lupus was evidenced in support of the belief that they are produced when the specific irritant is not powerful enough to effect a division of the cell protoplasm so fast as the nuclei are divided, — the specific irritant being the tubercle bacillus, and sparingly represented in lupus tissue.

Thus, it should be emphasized, that from a purely anatomical standpoint, lupus cannot be separated from tuberculosis. Baumgarten himself, who, as has been seen, was one of the chief opponents of the tuberculous theory from anatomical reasons, declares in his textbook that not the shadow of a doubt can now exist of its true tuberculous nature.

From the experiments that have been alluded to as proving that the epithelioid and giant cells of tubercle are in the main derived from a proliferation of the fixed tissue cells, and not from the emigrated white blood corpuscles, we may confidently assume that the newly-formed cells of lupus are produced in the same way. The first appearance of the lupus tissue is found to be an accumulation of cells, situated about the capillaries and lymph channels, in many cases representing a growth of the adventitia of these vessels. But all connective tissue cells that are affected by the virus of tuberculosis are capable of this metamorphosis, and in view of Baumgarten's experiments, the possibility that the epithelial glandular elements may also take part in the process cannot be excluded. Few studies of the histogenesis of lupus cells have been made in the light of the newer methods of staining and of the conclusions derived from experiments upon the iris. Unna in a recent paper has published the results of his investigations in this direction. He regards the epithelioid cells of lupus as identical with the "plasma zellen" of Waldeyer, and as distinct from Ehrlich's "mast zellen." These plasma cells, he says, represent the first stage of the cutaneous tubercle, and are not derived exclusively from the endothelium of the

capillaries, but from any of the fixed connective tissue cells. He finds nowhere any evidence of the transformation of wandering cells into epithelioid cells, as has been heretofore assumed; the few wandering cells found in the vicinity of the process are sharply distinguished by their small size and by their deeply-stained nuclei, from the epithelioid or plasma cells.

A point of considerable interest in Unna's investigations is his claim that the agglomerations of small, round cells found at the periphery of the lupus nodule are not leucocytes, as is even now assumed, but early derivatives of the epithelioid cells, as is shown by methods of protoplasmic staining. So much, at all events, seems to be settled—that the rôle of the leucocytes in lupus, as well as in other chronic inflammatory processes, has been greatly exaggerated, and that the fixed tissue cells are, at least in the main, the parents of the epithelioid and giant cell formations.

The next stage in the history of the lupus tubercle is the degeneration of the newly-formed cells and of the fibrillary tissue. The cells lying in the centre of the nodule are the first to be affected, their protoplasm becomes homogeneous, while the nuclei lose to a certain extent their susceptibility to staining. Following Weigert, the cells in lupus, as in internal tuberculosis, are regarded as undergoing a coagulation necrosis. Unna opposes this view, on the ground that no coagulation of the protoplasm can be determined, and that there is no death, as yet, of the cell. However, this question may be decided, the process is a degeneration of the tuberculous elements under the toxic influence of the bacteria, and represents the first stages of a necrosis, that is, on account of the small numbers of the bacilli, of slow progression—a stage that we never see in the acute forms.

Together with this degeneration taking place in the epithelioid cells, there is also a regenerative process. The cells are capable of proliferation, when not affected by the virus to the extent of advanced degeneration, and may finally become converted into connective tissue. In this manner is produced the lupoid scar-tissue, that takes the place of the lupus nodule, in the process of healing. Unna, in his work just referred to, regards the scar-tissue in cases of spontaneous healing of lupus infiltrations as different from that following an ordinary loss of tissue, in the fact that there is never a reproduction of elastic fibres, that the connective tissue is never arranged in intersecting bundles, but is placed horizontally to the surface, and that it contains numerous large "cell spindles," rich in protoplasm, which upon section give the skin a striped appearance. Hence he regards this cicatricial tissue as a true lupoid tissue, and not an indifferent substitute for the absorbed tuberculous elements.

An advanced stage of the regenerative process is seen in the elephantiasis that occurs in lupus. Here the tendency to the formation of new connective tissue is so great, and dominates the degeneration to such a degree, that large portions of the body are converted into dense masses of hypertrophied fibrous tissue, containing foci of degeneration to a greater or lesser extent, and presenting clinical appearances quite similar to those of advanced elephantiasis. This formation of new connective tissue in greater or lesser degree as compared with the necrobiosis is one of the causes of the multiplicity of clinical forms exhibited by the affection.

Another complication of lupus is the proliferation of epithelial elements that may take place. So far as our knowledge of the process extends, we must regard these phenomena as secondary and non-specific, caused by the irritation produced by the new formation, and analogous to the epithelial activity in syphilis and other chronic inflammatory processes. The rete may extend its interpapillary prolongations deep into the corium, and with the outgrowth of the papillae, that is so constantly allied to the epithelial proliferation in all papillomata, the clinical forms of lupus papillaris, verrucosus are produced. A proliferation of the glandular elements may also take place, as was emphasized long since by the studies of Lang.

When the tuberculous infiltration of the corium has reached a certain grade of intensity and the overlying epidermis has become stretched and thinned by the pressure from below, there frequently results a fracture of the epidermis, and the tuberculous foci are laid bare, giving rise to the forms of lupus ulcers. In these instances there frequently, if not usually, exists a complication with a septic process. To the presence of the pus micrococci we must refer all true supuration that attends a lupus lesion. The pus micro-organisms are very readily engrafted upon cutaneous lesions of any nature, and the tuberculous lesion shares with others the liability to this complication.

#### TUBERCULOSIS VERRUcosa CUTIS.

The last form of cutaneous tuberculosis, the anatomy of which we have to consider, is that affection first accurately described by Riehl and Paltauf, under the name of tuberculosis verrucosa cutis, a form nearly or quite identical with the anatomical wart so often found on the hands of those engaged in dissecting rooms and at the autopsy table. As described by Riehl and Paltauf the anatomical characteristics consist of greatly elongated and enlarged papillae, covered with a thickened, lamellated horny layer, which also fills up the depressions between the papillae. Between the cornified epidermal layers are found dried masses of exudation, with nuclei that are partially stained, and heaps of granular detritus. The interpapillary prolongations are hypertrophied and extend deeply into the corium in many places. The principal pathological changes are found in the upper layers of the corium, in the papillae and adjoining layers, which are filled with foci of closely aggregated cells. These foci consist of a granulation tissue made up of round cells at the periphery, large epithelioid and Langhans cells toward the centre, while the centre itself in the majority of cases is formed of a necrotic mass, indistinctly defined at its border. In a word, the histological appearances of tubercle are well defined. Besides these tubercles, foci of supuration are also found at the points where the epidermis has penetrated most deeply, which finally break through the overlying tissue and form small crypts filled with horny masses from the continued growth of the epidermis. The tubercle bacillus was constantly found in the nodules of granulation tissue. On the average, more bacilli were found than in lupus, but less than in the milium cutaneous form. Micrococci were found in all the parts where there was an acute inflammation and supuration.

These observations of Riehl and Paltauf have been verified by the most competent observers. The limits of their original description have been enlarged, in that these wart-like patches have been shown to occur

not only in adults who have had to do with animals and animal products, but in children and in people who have been exposed to direct infection from tuberculous excretions. The only question that can arise is as to the propriety of separating these cases from lupus verrucosus, a form which they often resemble very much both clinically and anatomically.

My interest in this form was excited some years ago and my conclusions are drawn from a considerable number of examinations of lesions, or portions of lesions, removed by the cutaneous punch and hardened and stained in various ways.

The occurrence of foci of acute inflammation immediately below the rete, and the formation of miliary abscesses was emphasized by Riehl and Paltanuf as one of the characteristics of this as distinguished from other forms of cutaneous tuberculosis, but was regarded as a secondary phenomenon and due to an invasion of the tissues by colonies of micrococci. In the more typical lesions, those first described by these authors as occurring upon the hands of adult butchers, cooks, etc., as well as in the anatomical wart, these inflammatory complications are indeed most marked. In many papillary growths, however, that undoubtedly belong to this class, this secondary inflammation is very slight or totally wanting, as was verified in a number of lesions that exhibited microscopically the histological appearances of tuberculosis and contained the tubercle bacillus. It may be fairly said, I think, that these inflammatory appearances are frequently found engrafted upon a tuberculosis verrucosa cutis, but their occurrence, in my experience, is not sufficiently constant to render their absence a point of consequence, and in any case they are secondary phenomena. They have not been present to any extent in the cases that I have examined occurring in children upon the hands, elbows, knees, etc., in the form described many years ago by Dr. McCall Anderson, under the title of lupus or scrofuloderma verrucosum. The histological appearances here give us a picture of nests of epithelioid and Langhans giant cells in the upper layers of the corium, with a papillary hypertrophy and an increase of cornified epithelium. Nor were these inflammatory appearances present in several cases of verrucous tuberculosis upon the bodies of people suffering from lesions of scrofuloderma or lupus of other parts. They seem to occur most frequently in the cases that present clinically the features of a typical verruca necrogenica.

With regard to the numbers of bacilli found, I have not been so fortunate as the writers quoted. While the detection of the specific micro-organism has been a comparatively easy matter in some instances, in others it has required a long and laborious search, equal to that demanded for their detection in lupus; and so far as my own researches go, I have not been able to demonstrate a striking divergence from lupus in this regard.

The chief anatomical characteristic that tuberculosis verrucosa affords in distinction from the papillary growths of lupus, is the *situation* of the tuberculous neoplasm. While the foci of granulation tissue lie in the lower and middle portions of the corium in lupus, in tuberculosis verrucosa, they are quite constantly found in the upper papillary layers, usually in the papilla themselves, and in this respect my experience accords quite exactly with that of Riehl and Paltanuf. It must also be admitted that in the form under con-

sideration, the papillary outgrowth occurs at a very early period, perhaps at the very beginning of the affection, while in lupus it is met with most frequently at a later period, when the tissues have become broken down and ulceration has taken place.

Anatomically, therefore, this affection differs from lupus papillaris chiefly in the superficial seat of the process. Many transitional forms may occur, and it may often be difficult to say, from a microscopical examination alone, which of the two varieties we have before us. Riehl and Paltanuf have undoubtedly brought into the limits of tuberculosis certain affections that were regarded before as doubtful or classed under other headings, and their work must be regarded as a distinct addition to our knowledge of the disease. For the present, at least, tuberculosis verrucosa cutis should be accorded a separate place among the varieties of this disease. Granting that the anatomical distinctions from a verrucous lupus are often slight, we have still the fact that these lesions were not, until the microscope taught us their histology, commonly classed with tuberculosis or lupus. A further argument in my mind for separating them from lupus, lies in the fact that the clinical evidence in these cases points to their being produced by *direct inoculation*.—a mode of infection that cannot as yet be demonstrated in a large number of lupus cases.

#### THE THERAPEUTICS OF CUTANEOUS TUBERCULOSIS.<sup>1</sup>

BY GEORGE HENRY FOX, A.M., M.D.,  
*Clinical Professor of Diseases of the Skin, College of Physicians and Surgeons, New York.*

In discussing the treatment of tuberculous affections of the skin, it will be convenient to consider first the local measures which may be employed, and then the constitutional remedies which may prove of service in facilitating a cure. In other words, we may regard the subject first from a surgical and then from a medical point of view. I will state at the outset, that I do not propose to even enumerate the various remedies and plans of treatment which have from time to time been recommended, but will confine myself to a discussion of those which have the sanction of high authority, and those which I have personally found to be of value.

As lupus vulgaris stands foremost among tuberculous affections of the skin, and as other forms of cutaneous tuberculosis are amenable to a like treatment, we will begin with the local therapy of this disease.

All are agreed, I think, that three objects are to be aimed at in the local treatment of lupus. These are (1) the removal of the morbid tissue, (2) with as little pain as possible, (3) with the least resulting disfigurement. A brief consideration of various methods in vogue will perhaps show how they fulfil these respective indications.

The oldest remedy in the treatment of lupus and one still recommended by some surgeons, is the knife. This will certainly remove the disease when limited in extent, and with the modern improvements in skin-grafting, a patch of lupus of almost any size might be excised and the wound healed. But this cannot be accomplished without much dread and discomfort on the part of the patient, and where a plastic operation

<sup>1</sup> Read at the Annual Meeting of the American Dermatological Association in Washington, September, 1901, introductory to the discussion upon the treatment of Cutaneous Tuberculosis.

on the face is involved, the result is seldom satisfactory from a cosmetic point of view. The prevalent fear of the surgeon's knife may be irrational, but it exists, nevertheless, and, in spite of the favorable results reported by Hahn, Seuger and others, in no case of lupus, large or small, in my opinion, preferable to other methods of treatment at our command.

The cautery, as commonly employed, is another agent, which I would unhesitatingly condemn. Acting equally upon healthy and diseased tissue, it must either produce an unnecessarily deep ulcer, or else the smooth, superficial and delusive cicatrix will soon appear studded with isolated nodules. Whether a Paquelin or galvano-cautery be used the operation is generally painful and the result either uncertain or disfiguring.

Doubtless the best method of employing heat in the treatment of lupus is that advocated by Besnier, and one which I must frankly confess, I have never fairly tested. This method consists in making punctate and linear scarifications by means of variously shaped needles, knives and buttons of platinum, connected with a galvano-caustic battery. Being sceptical as to the danger of general tuberculous infection resulting from blood-letting operations, such as scraping and scarification, I have failed to appreciate the advantages claimed by Besnier for his method of treatment.

The use of the flat electrode for the destruction of lupus tissue, as endorsed by Dr. G. T. Jackson, at the last meeting of our Association, I have tried repeatedly. There is no doubt as to the good result that can be obtained by this method, but the time required to effect the result is so great as to render the method of comparatively little value.

The curette is an instrument well deserving the high reputation it has acquired in the treatment of lupus. When used alone it is apt to prove insufficient to effect a cure. It usually removes the greater portion of the diseased tissue with ease, and when cocaine is injected or even applied on pledgets of cotton to the new surface, a large patch may be scraped with but little pain or discomfort to the patient. The healthy tissue remains uninjured, and a wound is left, which properly dressed, will heal speedily and leave a smooth cicatrix. The size and shape of the curette is largely a matter of taste, but the form of the Volkman spoon can hardly be improved. For recurrent isolated nodules appearing in the cicatrix after a previous unsuccessful operation, and for the minute points of diseased tissue noted after multiple scarification, even the smallest curette is apt to prove too large.

Here a dental burr or a dental excavator can be used to great advantage. Indeed, whenever lupus appears in the form of disseminated nodules, burrs of varying size will be found greatly superior to a small curette. With such an instrument many small and deeply-seated nodules of lupus can be bored out which would escape the action of any scraping process. Since recommending the use of the dental burr six years ago in the *Journal of Cutaneous and Venereal Diseases*, I have used it many times and with the greatest satisfaction. Until quite recently I was unaware that Mr. Morris, of London, had previously devised a similar instrument for this purpose. This is a double-screw excavator in which the lacerating edges are arranged around a cone in the form of two parallel spirals. It is claimed that as the pitch of each

spiral considered separately is double that of the single threaded screw, the cone can be inserted to its full depth with fewer turns of the instrument, thus reducing the duration of the operation and the suffering of the patient by fully one-half. It seems to me that this advantage is wholly theoretical and that the ordinary burr obtainable from any dentist or dental instrument dealer will fully answer the purpose.

As regards scarification in the treatment of lupus, too much, I think, has been said in its favor, while the objection raised against it, that it promotes the absorption of bacilli and leads to pulmonary tuberculosis is largely hypothetical. Linear scarification, as advocated by Squire and Vidal, is certainly an improvement upon the punctiform scarification employed by Dubini, Volkman and Veiel. There is no doubt but that it will cure lupus in most cases, and leave the most satisfactory cicatrix, but this method of treatment involves usually an amount of time and patience which greatly lessens its value as a therapeutic measure. The only cases in which it is superior to other plans of treatment are those of ulcerating lupus of the nose. Here the curette and various applications which tend to remove the diseased tissue are liable to cause considerable deformity, and cause the patient to go through life with a misshapen or stumpy nose. Scarification, however, in such cases, while it gradually destroys the lupus, permits a new growth of connective tissue to take its place, which tends to preserve the size and form of this important feature. As Vidal has shown by microscopic observation, the lupus cells gradually alter their configuration and assume the shape of fibres of connective tissue, and, as Squire has claimed, the nose may often be actually rebuilt.

Of caustics and various applications which tend to destroy lupus tissue by virtue of their chemical effect, a long list might be given. All have proved of service in certain cases; few have manifested any remarkable and distinctive therapeutic value, while none have as yet found their way into general favor. I will merely mention nitrate of silver, caustic potash, chloride of zinc, lactic acid, ethylate of sodium, iodoform and aristol, and remark that in spite of time-honored usage or eminent recommendation, they possess no special value in the treatment of lupus, and in many respects are greatly inferior to remedies of which I shall presently speak.

The use of bichloride of mercury, on account of its bacillicide properties, has been advocated by Doutrelepon, Tansini, White and others. My own experience with this method of treatment has proved unsatisfactory, and the slight improvement which took place in a few cases appears to be due rather to a stimulating effect such as would follow its application to the nodules of acne or rosacea, rather than to any parasiticide action. The reported experience of others has been similar to mine.

Of the various substances applied to ulcerating lupus and to the curetted surface, with a view to the complete destruction of the lupus tissue, no one has perhaps met with greater favor than pyrogallol. This was introduced by Jarisch, who recommended a ten per cent. ointment to be applied twice daily, after thorough curetting of the patch. At the end of three to five days, or when the surface appears swollen and of a dirty grayish hue, iodoform is to be plentifully applied, which tends to check the pain produced by

the ointment. This is covered with linen smeared with boric acid ointment, and bandaged for several weeks, until the suppuration lessens and healing begins. Mercurial plaster is now applied, and after four or five weeks the same cyclus of curetting, pyrogallol, iodoform with boric acid dressing is repeated in order to prevent the return of the lupus in the form of milary infiltration. Finally, the wound can be healed rapidly by skin transplantation.

For many years I have had more satisfactory results from a somewhat similar plan of treatment than from any other method which I have employed. I have, however, used a much stronger ointment of pyrogallol, varying from twenty-five to fifty per cent., which greatly shortens the duration and adds to the efficacy of the treatment. The application is sometimes quite painful for the first twenty-four or forty-eight hours, and may give rise to considerable inflammation of the part. But the continued use of the strong ointment soon produces a numbing sensation in the locality to which it is applied, and no further complaint of pain is made until the ointment is discontinued and a simple dressing is substituted. This application, coinciding with the separation of the sloughing tissue, will often be regarded by the patient as more painful than the pyrogallol. When the dirty, brownish, putrescent slough has separated and left a clean, raw surface, mercurial plaster may be applied, beneath which the ulcer will become converted into a smooth, pliable cicatrix. Or, if the raw surface be considerable in extent, Thiersch's method of skin transplantation may be employed with benefit. I have no hesitation in recommending this use of (1) the curette, (2) the strong pyrogallol ointment, and (3) the mercurial plaster as a most admirable method in the treatment not only of lupus but of rodent ulcer. It is a method which has many advantages and few objectionable features.

Salicylic acid is a remedy which experience has proved to be of service in the treatment of lupus and other forms of cutaneous tuberculosis as well as in many other affections of the skin. In a letter to the *British Medical Journal* in 1884, it is recommended in the treatment of lupus vulgaris, by Dr. J. G. Marshall. In a paper published in the London *Lancet* in 1886, Unna advocates its use in most enthusiastic terms. He recommends the application of varying strength, but all containing two parts of beech tar creosote to one part of salicylic acid. The pain caused by the acid alone is very severe, and constitutes a serious objection to its use, but it is greatly mitigated by the anæsthetic action of the creosote, which Unna speaks of as the "morphine of the skin." The creosote has an antiseptic and bacillicide effect, and is therefore both corrugent and adjuvant to the salicylic acid. A strong plaster is at first applied to destroy the epidermic covering of the lupus tissue. Before the second plaster is applied to the raw surface, a solution of cocaine may be employed, which will temporarily deaden the pain, which in a short time yields to the more lasting anæsthetic effect of the creosote. The remedy leaves a smooth cicatrix, but according to Unna, redness of the scar is apt to persist for some time, owing to a paresis of the capillaries or destruction of the stratum granulosum.

I have used this combination of salicylic acid and creosote in an Irish-moss plasma, and so far, with satisfactory results, but my experience with it has not

been sufficient to say whether or not it is equal in value to pyrogallol.

I will mention but one more local remedy which, in the case of one of my lupus patients at the New York Skin and Cancer Hospital, has produced a remarkably beneficial effect. The remedy is fuchsine. The patient, a man of about thirty-five years of age, had suffered from lupus of the right ear and neck for eight years. Surgical measures had been employed by one or two dermatologists with no marked results. Injections of Koch's lymph were employed for two months or more at St. Luke's Hospital, and although the reaction was characteristic, the patient was finally discharged with no apparent improvement. He now entered my service at the Fordham branch of the Skin and Cancer Hospital, where for the past three months the fuchsine treatment has been faithfully carried out by Dr. A. C. Lewis. The surface of the affected skin or a portion of it has been very superficially scarified with a scalpel twice a week, and a one per cent. alcoholic solution of fuchsine painted over the part. The treatment has been almost painless, but nevertheless the elevated lupus tissue has completely flattened, and now only dull red patches are to be seen. The prospect of an absolute and speedy cure in this case seems quite encouraging.

The constitutional treatment of cutaneous tuberculosis may be conveniently divided into the specific and non-specific, the former aiming at a direct action upon the morbid growth, the latter merely improving the general condition of the patient and thereby modifying the soil upon which the tuberculosis is implanted.

Despite the vagueness of the term there is certainly such a thing as scrofula. It is an inherited or acquired condition of certain tissues, which leads to the development of definite and characteristic symptoms. It doubtless renders the subject of this diathesis especially liable to the engrafting of tuberculosis in the strict sense of this term. Although no one can assert that cod liver oil or iodine or the hypophosphites have ever produced the slightest direct effect upon lupus or other tuberculous lesions, there is no question as to the value of these remedies in combating the scrofulous diathesis. In the therapy of cutaneous tuberculosis, these remedies may therefore be justly considered as prophylactic, and clinical observation has repeatedly shown that in certain cases they are a valuable and often indispensable adjuvant to local measures. Without discussing this subject at length, I would merely take this opportunity of expressing my firm belief in the value of iodide of starch as a reconstructive agent in all cases of struma, whether tuberculosis be present or not. In 1880, McCall Anderson advocated the use of this remedy in erythematous lupus, and strangely enough implied that it was of no value in lupus vulgaris. His formula consisted of twenty-four grains of iodine to an ounce of starch, the iodine to be triturated with a little water, and the starch to be added slowly, the mass to be dried by a gentle heat, and kept in a close-stoppered bottle. By use of this remedy, he claimed that the largest amount of iodine could be most easily introduced into the system. I have used this remedy freshly prepared, with great satisfaction, and I think with great benefit, not only in cases of lupus vulgaris, but in many cases of acne occurring in lymphatic subjects, and also in cases where chronic syphilis is combined with struma.

We come now to the specific treatment of cutaneous tuberculosis, and the method promulgated a year ago by Robert Koch, is the only one which seems worthy of discussion. As to the precise action of tuberculin in tuberculous and healthy subjects, there are many questions of greater or less scientific importance which as yet remain unsettled, but sufficient time has elapsed and sufficient experience has been acquired to enable an unprejudiced student of therapeutics to form at least an opinion, if not a definite judgment, upon this novel method of treatment.

In Europe, according to the various published reports, a most remarkable diversity of results has followed the employment of lymph injections in the treatment of tuberculosis. As geographical locality can certainly exert no influence upon the therapeutic method in question, and as men of science profess to acknowledge but one brotherhood and one Fatherland, it is simply astounding that such conflicting observations should have been made upon different sides of the Rhine. While some will explain this diversity of opinion by reference to national pride and national enmity, others may perhaps conclude from a study of the published reports, that Koch's lymph is a divine remedy for the tuberculous German, but sure death to the tuberculous Frenchman.

In this country the introduction of Koch's method has been followed by a most decided reaction. The public press, which went fairly wild over the startling novelty, would now scarcely devote a paragraph to a dispassionate statement of its value. The numerous members of the profession who thronged our public hospitals and gazed in awe at a simple hypodermic injection, or offered fabulous prices for a few drops of the lymph, are now busied with newer remedies, and would not buy the lymph if it were offered at ten cents a gallon. But this does not in the least affect the question as to whether tuberculin is or is not a remedy of practical value in the treatment of tuberculosis.

The experience of physicians in this country, where national feeling plays little or no part in determining the final judgment in the matter, ought to prove of exceptional value, and the expressed opinion of members of this Association, however various it may be, will doubtless serve to mould medical opinion on this side of the Atlantic.

My own experience in the use of tuberculin has been limited to a few cases in my service at the New York Skin and Cancer Hospital, including lupus vulgaris, lupus erythematosus, sarcoma and leprosy, while a few more of my patients were kindly treated for me by Dr. Kinnicutt, at St. Luke's, and Dr. Bailey, at the Post-Graduate Hospital. These include cases not only of both forms of lupus, but also of eczema, epithelioma, and syphilis. I need not give detailed histories of any of these cases, but will simply speak briefly of the general results attained and conclusions formed. None of the alarming effects reported by many others occurred among my cases, probably from the fact that I limited myself to the use of small doses, injecting one milligramme, or even less, at the outset, and rarely increasing the dose above ten or fifteen milligrammes. In one very nervous patient with erythematosus lupus of the cheeks, the first injection was followed by an attack of hysterical epilepsy, the patient having a series of rather severe opisthotonic convulsions during the succeeding twelve hours. That the lymph, however, was not the direct cause of these unexpected symp-

toms, was proven later by a series of milder convulsions which followed the injection of pure water. A somewhat remarkable subnormal temperature followed the second or third injection in a case of leprosy of the tubercular type, the house-physician asserting that the careful use of a reliable thermometer showed the figure to be 94°.

In my lupus cases, to which I shall restrict my remarks, the local and general reaction occurred in a characteristic but mild form, but with the exception of two cases, no decided curative effect was produced. In one of these, vigorous curetting had been employed a short time before, and the cheek presented a group of pinkish nodules which were largely cicatricial in character. Reaction occurred after the first injections and then ceased. In this case, though the patient was discharged as cured, but little if any credit could justly be awarded to the action of the lymph.

In another case, of a young woman whom I had treated for lupus of the nose, simply with the dental burr and without affecting a complete cure, a steady and decided improvement occurred from injections made at the Post-Graduate Hospital. The small nodules flattened and disappeared, leaving only a congested cicatrix, and a few suspicious points. During the past few months, however, in which I have done nothing but watch the case with interest, these suspicious points have faded, and the lupus now appears to be permanently cured. This patient might have been more speedily cured by curetting and the use of pyrogallol or salicylic acid, but a more noticeable scar would doubtless have been left.

In other cases of lupus under my care or observation, no approach to a cure occurred in spite of numerous repetitions of both local and general reaction. When reaction ceased altogether, and the lesions appeared as prominent or even more so than at the outset, it was natural to conclude that no good had been accomplished and that Koch's method, in these cases at least, had proved a failure. I wish to condemn such a hasty conclusion, for I believe that good results have been accomplished in some cases, although they were not apparent upon the surface. The first case of lupus injected in New York was a young woman with a patch involving the ear and a portion of the cheek. She had been treated for several months at the Skin and Cancer Hospital, with but slight improvement, and was placed in Dr. Kinnicutt's care at St. Luke's, for lymph treatment. For a month the prospects of a speedy cure were brilliant, as the reactions were typical and decided, and improvement began to manifest itself. Reaction then ceased, no further improvement occurred, hope gave way to discouragement, and after about three months the patient was sent back to me. I now resumed the previous surgical treatment with the burr, and found that the lupus tissue beneath the surface had been softened to such a degree that it could be much more readily destroyed. The patient is now about well, and although the treatment may have been a trifle more energetic than before the lymph was used, I am convinced that the present successful result is largely due to its beneficial effect.

Another case of long-standing lupus treated at St. Luke's, was finally discharged and sent to me with a note from Dr. Kinnicutt, saying that there was no reason for pursuing the treatment by injections of lymph. This is the case to which I have already referred as being nearly well under the fuchsine treat-

ment. As fuchsine has been used in lupus without success, I am inclined to believe that the notable effect produced in this case may be due in some measure to a change in the lupus tissue produced by the injections.

In the great hospitals of Paris, Vienna and Berlin, Koch's remedy has been tested upon a more extensive scale than in this country, and observations have been made with the greatest care. In this great trial involving the question of life or death, to a large proportion of suffering humanity, it may be said that the jury has disagreed. A commission of eminent physicians of the Hôpital St. Louis, after an experience based upon the treatment of fifty cases, has reported in terms of unqualified condemnation. Kaposi, in Vienna, after an experience in fifty cases (thirty-five of which were lupus vulgaris), reports that many unpleasant general effects were produced by the injections. Though reaction occurred in non-tuberculous cases, it was not as prompt, intensive and constant as in lupus vulgaris. In this disease the lymph worked promptly in producing a superficial, temporary inflammation, followed by a notable flattening, loss of color, and improvement within a few weeks. But no cure was effected. He asserts that the lymph will not take the place of other remedies, upon which reliance must still be placed, and adds that it remains yet to be determined in what manner and to what degree a methodic alternation and combination of Koch's method with those previously employed, may prove advantageous in the therapy of lupus. Neumann states that in the majority of cases repeated injections exert a specific action upon lupus tissue, obtained by no other method of treatment heretofore employed, and the use of the lymph in certain cases of lupus produces an improvement, and in many localities effects a cure. He adds that from henceforth no specialist will fail to test tuberculin before resorting to the old methods of cauterizing and scraping, and claims that with no other method has he succeeded in four months in effecting such an improvement in certain cases as has resulted from the lymph injections. In the official report of the Prussian Universities on the action of Koch's remedy for tuberculosis, favorable reports are received from the dermatological clinics. Doutrelepoint, of Bonn, says: "Our observations fully confirm the statements of Koch. . . . Our lupus cases all heal under the use of Koch's remedy. . . . The treatment of tuberculosis by Koch's lymph is to be considered as one surpassing all previous methods, both as to the length of treatment and the beauty of the resulting scars."

When doctors disagree, who shall decide? In default of a unanimous verdict from such authoritative sources as have been mentioned, it remains for each to test Koch's remedy for himself, and to arrive at an independent conclusion.

A NEW terror of courtship has been developed in the case of an Indiana brunette. For some days she had suffered from a supposed attack of pleurisy, but when Dr. S. F. Bordman was called in he found that one of the young lady's ribs was fractured. After much questioning, the girl blushing admitted that her best beau had inflicted the injury while giving her his usual tender embrace before parting on his last visit. The occurrence of the accident was marked by a sharp pain in the side, a "catch in her breath," and a sudden relaxation of her hold.

## Reports of Societies.

### AMERICAN DERMATOLOGICAL ASSOCIATION.

THE Fifteenth Annual Meeting was held at Washington, September 22-25, 1891, in conjunction with the Congress of American Physicians and Surgeons.

#### FIRST DAY.

The meeting was called to order by Dr. F. B. GREENOUGH, of Boston, who made the

#### OPENING ADDRESS.<sup>1</sup>

The Report of the Committee on Nomenclature was made, and after discussion was accepted.

The first paper read was by Dr. H. G. KLOTZ, of New York, entitled

#### DERMATITIS HEMOSTATICA.

It was discussed by Drs. Piffard and Bronson.

Dr. L. A. DUHRING, of Philadelphia, followed with a paper

#### REPORT OF A CASE OF UNIVERSAL ERYTHEMA MULTIFORME.

It was accompanied by a colored portrait of the case and specimens of large plates of exfoliated epidermis shed by the patient during the latter part of the course of the disease. It was discussed by Drs. Hyde, Duhring, Sherwell, Shepherd, Fox, Allen and Bronson. Dr. Shepherd asked if any drug had been administered for the rheumatism that was a marked feature in the case, to which Dr. Duhring replied, "No! The treatment had been entirely negative." Dr. Fox had seen a case somewhat resembling that of Dr. Duhring, in which there was a question if the eruption had been caused by some drug that had been taken for a co-existing gonorrhœa. He thought that it was a purely accidental occurrence. We often see cases of dermatitis exfoliation following other diseases such as psoriasis.

Dr. SHEPHERD, of Montreal, then read a paper upon

#### AN UNUSUAL CASE OF SARCOMA, INVOLVING THE SKIN OF THE ARM, REQUIRING AMPUTATION.

This was followed by a paper by Dr. S. SHERWELL, of Brooklyn, upon

#### MULTIPLE SARCOMATA. HISTORY OF A CASE SHOWING MODIFICATION AND AMELIORATION OF SYMPTOMS WITH LARGE DOSES OF ARSENIC.

The author after pointing out numerically several interesting points, chief among which were, largeness of therapeutic dosage, tolerance of them by patient, complete and rapid subsidence of tumors under such dosage, rapid recurrence under suspension of same, originality of treatment instituted, etc., goes on to give a history of the patient with sarcomata, supplemented with a further history by Dr. John B. Wheeler, of Burlington, Va.

Dr. Sherwell removed in all from this patient thirty growths, some of which were quite large, one three and a quarter inches in diameter; Dr. Wheeler, about a year later, in a series of operations, removed the immense number of one hundred and seventy, large and small. In the interval between his leaving Dr. Sherwell's care and coming under that of Dr. Wheeler,

<sup>1</sup> See page 340 of the Journal.

he had interrupted or almost suspended treatment spoken of above, which had at the time of his leaving Dr. Sherwell caused the complete or almost complete disappearance of all growths. They recurred too rapidly for Dr. Wheeler to operate, when he adopted the same internal treatment as that which Dr. Sherwell had instituted, with the most decided and gratifying results, namely, the same rapid disappearance of the growths. The case ended by his leaving Dr. Wheeler's care in good condition, and doing exceedingly well, irregularly or total interruption of treatment, and, as before, recurrence of growths, followed in a few months by death.

In the discussion, Dr. Zeisler mentioned brilliant results in a case of lupus sarcoma, for the administration of arsenic. In a case of pigmentary sarcoma, he had given the drug without effect. Dr. J. C. White, of Boston, had seen good effects from use of the drug in one case of sarcoma. Dr. Robinson, of New York, had not had much success with arsenic. He believed that many cases of multiple sarcoma were in reality microbean in origin and not true tumors.

The next paper read was by DR. R. B. MORISON, of Baltimore, on

#### THE HYPODERMIC USE OF HYDRARGYRUM FORMIDATUM IN SYPHILIS,

which he recommended as a treatment of great usefulness, especially as a means to fall back upon in some cases in which older forms of treatment did not succeed, or in which such a plan as that of inunction was not practicable. He always used Merck's preparation and found that it did not cause much pain nor prove objectionable. He had never used any of the insoluble salts. In the discussion, Dr. Corlett said that he had found hypodermic injections of mercury of great use in some cases, such as in those cases in which the stomach has given out. Dr. Klotz had employed hypodermic injections in syphilis. While it was doubtless of value in some cases, for most cases older methods of treatment are quite as good. Dr. Greenough said that while greatly interested in the subject of hypodermic medication in syphilis, he had found it impossible to get his patients to submit to it. He thought it was useful only in exceptional cases in which other plans could not be used. Its ultimate result was no better than that of other plans.

DR. J. GRINDON, of St. Louis, read a paper upon

#### LICHEN SCROFULOSORUM,

which gave rise to a long discussion. Drs. Robinson, Piffard, Sherwell, Shepherd, Corlett, Bronson, and Greenough, all had seen cases of this rare disease.

#### SECOND DAY.

The Committee on Statistics made its report through its chairman, DR. J. N. HYDE, of Chicago.

This was followed by a discussion on

#### TUBERCULOSIS OF THE SKIN,

which was opened by DR. J. C. WHITE,<sup>2</sup> of Boston, who presented "Its Clinical Aspects and Relations"; by DR. J. T. BOWEN,<sup>3</sup> of Boston, who presented "Its Pathology"; and by DR. G. H. FOX,<sup>4</sup> of New York, who presented "Its Treatment." In the discussion, Dr. H. G. Piffard drew attention to the fact that

French and other competent observers had surmised the connection between what was then called pulmonary consumption and lupus and the so-called scrofuloderma. He himself had done so in 1876. Recent invention of the Abbe condenser and Zeiss lenses had enabled us to discover the tubercle bacillus, and to establish the relationship on pathological grounds. He himself believes that lupus erythematosus is fully entitled to the name "lupus," as he thinks that it, too, is of bacillary origin. Nor is he alone in his opinion. Cold abscess of the skin is probably due to the same cause, as is also rodent ulcer. He would agree with Dr. White in believing that we should have some collective term for all the various tubercular diseases. In treatment he would advocate cutting out the whole diseased patch, unless it was very extensive. Next to the knife he would place the actual cautery, after removal of as much as possible of the growth with the curette. Arsenic and chloride of zinc are also to be depended on.

Dr. C. W. Allen commended multiple scarification; and combined pyrogallol and mercurial plasters; he thought that there might yet be a future for Koch's tuberculin.

Dr. J. Zeisler was in thorough accord with Dr. White. By his experience at the Hôpital St. Louis, he had become converted to the use of the galvanocautery. He would also testify to the efficacy of the solid nitrate of silver stick, which, bored into the skin, would act both as a knife and caustic. He was not enthusiastic as to tuberculin.

Dr. E. B. Bronson believed that it was best to retain for some time our present terminology for the different tubercular diseases. In regard to tuberculin, he had seen improvement in some cases treated with it, but on the whole his experience had made him regard the remedy unfavorably. He had had good success with the dental burr, as first advocated by Dr. G. H. Fox. The nitrate of silver stick was also good.

Dr. J. N. Hyde was glad that Dr. White had come to accept local contagion as the cause of lupus, a view that he himself was among the first to advocate. He thought that in this country there were but few cases of lupus with a history of pulmonary tuberculosis in the family, or with tubercular diseases elsewhere. He did not believe in the treatment by scarification. Both the curette and nitrate of silver were serviceable in proper cases. In regard to tuberculin, he thought it possible that in time we might find something of value in it, but it was not so now.

Dr. L. A. Duhring would retain the old names for some time to come. He had not found lupus associated with general tuberculosis in private practice. He would recommend pyrogallol most highly, using it in the form of a plaster with resin and soap plaster, three of the resin plaster and one of the soap plaster. This is to be worn continuously. Local use of bichloride of mercury he had not found beneficial. Tuberculin he had found helpful, though he did not report any case of cure.

Dr. P. A. Morrow would agree with Dr. White that as lupus and some other diseases had a common etiological factor, we should place them together under a common heading. He advocated the use of multiple scarifications followed by mercurial plaster. For destruction of the small lupus nodules he recommended punctate cauterization with a white-hot instrument. Chloride of zinc was superior to pyrogallol as a caus-

<sup>2</sup> See page 509 of the Journal.

<sup>3</sup> See page 510 of the Journal.

<sup>4</sup> See page 521 of the Journal.

tic. Excision will probably increase in favor as the means of treating lupus.

Dr. A. R. Robinson would not include lupus under a common heading with tuberculosis on account of its different clinical aspect.

Dr. H. G. Klotz was not yet satisfied with our present knowledge of the infection of the skin with bacillus tuberculosis.

Dr. L. D. Bulkley is not satisfied with any of the plans for the external treatment of lupus. Internally, he has great faith in phosphorus as a curative agent, the nodules softening up and disappearing under its continuous use. He would corroborate Dr. Fox's advocacy of fuchsine. As to pyrogallol, that, too, was admirable. He applies it in powder form, pure, after scraping. Salicylic acid combined with pyrogallol, is also useful.

Dr. S. Sherwell was doubtful of the relationship of tuberculosis to lupus.

### THIRD DAY.

Dr. DUHRING read a paper upon

#### NOTES OF A VISIT TO THE LEPROS HOSPITAL OF SAN REMO, ITALY.

In reply to a question by Dr. White, after the paper was read, he replied that no attempt at segregation was made in San Remo. There were but few cases in the Hospital, and they were in an ordinary ward of a general hospital. They were not permitted to leave the confines of the hospital.

Dr. P. A. MORROW, of New York, then followed with a paper on

#### SKIN GRAFTING,

and showed a case in which the operation had been done by the method described by him, and with admirable results.

In the discussion of the case Dr. Duhring spoke in high praise of the operation of skin grafting as practised by Dr. Jas. E. Garretson. Dr. Clarke asked if Dr. Morrow thought that the inclusion in the graft of the deeper structures of the skin, as recommended by him, would give any better results than more superficial ones. To this Dr. Morrow replied that he thought they would be more certain to take, and he had not had a single failure. He had made more than fifty grafts of hairy skin upon a cicatricially bald scalp, and all of them had taken, and from many of them the hair was growing nicely. Dr. Sherwell had had good results also, by deep grafts.

Dr. P. A. MORROW, of New York, then read a paper on

#### THE TREATMENT OF ALOPECIA AREATA,

and was followed by Dr. L. D. BULKLEY, of New York, with a paper on

#### A THERAPEUTIC NOTE ON ALOPECIA AREATA.

The two papers were discussed together. Dr. J. Zeisler believed alopecia areata was due to a parasite, though there were some cases due to a neurosis. The latter were the very obstinate ones. He was in favor of treating all cases by epilation about the patches. With pilocarpine he had had no success. He regarded the use of a concentrated solution of common salt as a good remedy for stimulating hair growth.

Dr. W. T. Corlett spoke in favor of acetic acid as a remedy in alopecia areata. Cases, however, recovered spontaneously.

Dr. G. H. Fox was always pleased to hear any one speak with confidence of any treatment of alopecia areata, as Dr. Bulkley had done of carbolic acid. He was rather sceptical of any remedy. A strong solution of ammonia had proved as effective as any in his hands. He thought that general treatment of the patient was quite as important as any local application. Dr. J. E. Graham had never seen any cases that would lead him to believe that alopecia areata was contagious. He did not think that because antiparasitic remedies were useful, that this was a proof of the parasitic nature of the disease. Dr. P. A. Morrow thought that there had been a sufficient number of cases of contagion reported to satisfy any reasonable doubt of the contagiousness of the disease. He quoted Eichhoff's report, in which a number of cases were traced to one barber. He had had one case of probable contagion.

Dr. L. A. Duhring said that, in spite of a great deal of study of alopecia areata, he had never been able to find any parasite in the disease, nor to be convinced that the disease was contagious. He believed that there was a disease simulating alopecia areata, and often reported as such, that sometimes occurred epidemically, but was not alopecia areata. He regarded arsenic taken internally as very valuable in the treatment of the disease. He could see no reason for depilating the healthy hair about the patches.

Dr. J. C. White said that we were still wanting positive evidence of both the parasitic and the neurotic element in the etiology of the disease. Clinical evidence points both ways. He had seen cases of apparent contagion. He had seen thirty cases of a disease simulating alopecia areata, and that were not cases of ringworm, occurring in an asylum which probably were instances of the so-called contagious alopecia areata. He did not think that they were true alopecia areata. His favorite remedy was half a drachm of croton oil to eight ounces of turpentine used daily. Of course it failed in some cases, as do all remedies. If it failed, he used many other remedies that had been commended, but they did not do any better. He did not believe that there was any specific remedy.

Dr. H. W. Stelwagon had never been able to trace a case to a contagious origin. Local stimulation is more to be relied on in treatment. He was fond of equal parts of turpentine, cantharides and tincture of capsicum, with arsenic internally.

Dr. J. N. Hyde believed that the time would come when alopecia areata would be regarded as simply a symptom. Some cases were doubtless parasitic and some neurotic in origin. In bad cases he used creosote locally. After, say the forty-fifth to the forty-eighth year of life the chances of recovery were greatly decreased.

Dr. H. G. Klotz had had one case in which hereditary syphilis was probably the underlying cause, the boy getting better when under specific treatment.

Dr. C. W. Allen believed that the disease was parasitic, and thought that he had in his own practice observed a case of contagion. He thought that internal treatment was valuable. Naphthol and pyrogallol had both proved useful in his hands.

Dr. S. Sherwell believed the disease to be of neurotic origin alone. Stimulation was most to be depended on.

Dr. J. Grindon had never met with a case that suggested either a parasitic or contagious origin of the disease. He believed in its trophoneurotic origin.

Dr. F. B. Greenough used in practice a half-drachm of carbolic acid in an ounce of water.

Dr. L. D. Bulkley in reply to a question of Dr. Morrow, said that he used the ninety-five per cent. solution of carbolic acid only to a small portion of the scalp at a time. It should be brushed over lightly at first so as to benumb sensibility, and then rubbed in more thoroughly. He had not used it elsewhere than on the scalp. The skin is red for a few weeks; this disappears and the hair grows. He also administers strychnia and phosphoric acid, and keeps up the nutrition of the patient.

Dr. R. W. TAYLOR, of New York, read an account of a case of

#### ANGIOMA PIGMENTOSUM ET ATROPHICUM,

by Dr. A. W. BRAYTON, of Indianapolis. It was accompanied by an excellent portrait.

Dr. J. C. White stated that his investigations showed that the disease was not limited to Russian Jews, but was met with also in persons of English and French descent.

Dr. BRONSON then read his paper upon

#### THE ETIOLOGY OF PRURITUS.

The afternoon session began with a short discussion of Dr. Bronson's paper on pruritus, in which Drs. Zeisler and Morrow took part, the discussion being closed by Dr. Bronson.

Dr. W. T. CORLETT, of Cleveland, then read a paper upon

#### DISEASES OF THE SKIN, ASSOCIATED WITH DERANGEMENT OF THE NERVOUS SYSTEM.

It was discussed by Drs. Bronson, White, Fox, Duhring, Zeisler, Allen and Sherwell, who took various views of the cases reported, all agreeing that it was very difficult to diagnose what the cases were without having seen them.

Dr. L. A. DUHRING read his paper entitled,

#### EXPERIENCES IN THE TREATMENT OF CHRONIC RINGWORM IN AN INSTITUTION FOR BOYS.

He recited the many remedies he had used. In the discussion Dr. G. H. Fox said that Dr. Duhring's experience was both interesting and valuable. He had had considerable experience in the New York Skin and Cancer Hospital. He had found chrysarobin useful, as had Dr. Duhring. He began the treatment by clipping the hair short, and shaving, either only over the patches or over the whole scalp and applying chrysarobin in traumatism. He was tired of greasy applications. Hydronaphthol plaster, as recommended by an European physician, had proved more satisfactory than chrysarobin. He advocated epilation where practicable.

Dr. J. Zeisler advocated pyrogallol as a parasiticide. Dr. Duhring, in reply to a question, said that some of the cases recovered in six weeks, and some not for a year. Dr. White thought that white chrysarobin was a good remedy; it was not a safe one to use outside of an asylum or hospital. He recommended a combination of sulphur, carbolic acid and naphthol in ointment form. Dr. Stelwagon recommended an ointment composed of tar, sulphur and citrine ointment. Dr. Sherwell advised keeping the scalp saturated with a mild oil, and covered by a skull cap. Dr. E. Wigglesworth believed that it is necessary for us to have regard to the nutrition of our patients. Dr. C. W. Allen

bore testimony to the value of chrysarobin. Dr. L. A. Duhring, in concluding, said that the cases were all well when he left off treatment and that they remained well for at least one year. Epilation he found did not repay the vast amount of labor it cost. He regarded ointments as most useful remedies.

#### Dr. J. ZEISLER, of Chicago, then read his paper on EPILATION; ITS RANGE OF USEFULNESS AS A DERMATO-THERAPEUTIC MEASURE.

In the discussion, Dr. G. H. Fox said that he was glad to hear any one advocate epilation in sycosis, as he had found it a most useful remedy. A sulphur paste after epilation is valuable. He had not found epilation so promptly curative as had Dr. Zeisler, while he laid more stress on diathetic management than did the latter. He was sure that epilation was useful in some cases of chronic ringworm of the scalp. Dr. H. G. Klotz spoke also in favor of epilation in sycosis, though he had cured many cases without it, notably with mild naphthol ointments. He thought epilation to be valuable in syphilitic lesions about the hairs, as well as in all the pustular affections implicating the hair. Dr. L. A. Duhring had not been able to practice epilations on his patients on account of the pain it caused, specially on the upper lip. He could not see much use in depilating in alopecia areata when the hairs were firm about the patch. Dr. P. A. Morrow said that he did not think that it was necessary to pull out all the hairs about the bald patches, but it was a good thing to make traction on all of them and to remove all that were loose. Epilation was a requisite in all rebellious cases of trichophytoses. If the hair is removed by a quick sudden movement, the operation is nearly painless. Dr. H. W. Stelwagon believed that many cases of sycosis could be cured without epilation. He would speak in special praise of Fleming's solution in trichophytosis, diluting it at first one part to five or six of water, and gradually increasing the strength, to just short of marked irritation. Dr. S. Sherwell spoke of the connection between catarrhal conditions of the nose and sycosis of the upper lip. Dr. J. N. Hyde said that the last time he was in London and Paris he had observed that epilation was quite generally practised about the patches of alopecia areata. In closing, Dr. Zeisler said that when epilation was properly performed it was almost painless, as he regards alopecia as a parasitic disease spreading at the periphery he epilated about the patches to stop their spreading.

#### FOURTH DAY.

The first paper was by Dr. J. E. GRAHAM, of Toronto, upon

#### MOLLUSCUM CONTAGIOSUM.

Dr. Bowen said that there was little question but that the disease was contagious. It is still unproven whether certain bodies found in molluscum are or are not coccidiae. Dr. Allen had no doubt about the contagiousness of the disease and related cases of the disease spreading in an asylum from one case. Excision is never necessary. They can readily be squeezed out, and then lightly touched with a caustic. He believed in their parasitic origin. Dr. E. Wigglesworth likewise cited a case of contagion. Dr. J. C. White, while believing that molluscum was contagious, was not prepared to accept the psorosperm as its cause. Dr. J. N. Hyde pointed out that in the statistics for the year just closed, seventeen cases of molluscum contagiosum

were reported, namely, nine from Boston, five from New York, two from Chicago, and one from St. Louis. Dr. F. B. Greenough believed them to be contagious. In treatment, he simply bores them out with nitrate of silver stick. Dr. S. Sherwell concurred in the belief of their contagion. Dr. J. E. Graham thought from evidence so far brought forward that the so-called psorosperms were simply degenerated epithelial cells.

Dr. J. N. HYDE, of Chicago, then read an interesting paper,

#### NOTE RELATIVE TO PEMPHIGUS VEGETANS.

In the discussion, Dr. L. A. Duhring said that he had had the opportunity of seeing the case described, and would corroborate what Dr. Hyde had said of it. It certainly was more of the nature of pemphigus than anything else. Dr. Bowen had seen a case of Neumann's in Vienna, and this one brought that one back very vividly to his mind. He regarded the term "pemphigus" as a most indefinite one, and thought that it gave very little idea of the pathology of the case under discussion. Dr. S. Sherwell had seen a case with analogous symptoms in a woman, which was cured by ovariectomy. Dr. J. E. Graham related the history of a similar case of his own. It became much better under arsenic, but suffered a relapse. Dr. J. N. Hyde, in closing, said that in his case there was no disease of the ovaries. He regarded the prognosis in his case as not good.

Dr. H. W. STELWAGON, of Philadelphia, then read his paper on

#### A STUDY OF MYCOSIS FUNGOIDES.

It was discussed by Drs. Hyde, White, Hartzell, Bowen, Duhring, and Fox. Dr. Hartzell emphasized the infectious nature of the tumors, and thought that we must look to inoculation experiments for its proof. Dr. Bowen spoke of the disagreement among pathologists in regard to the exact nature of the tumors. Dr. Duhring said that the disease was a general one of the skin, and did not seem to affect other organs to any extent. He believed it to be an infectious disease. It may be regarded as on the border line between an inflammatory new growth and a tumor. Dr. Fox related a case of apparent infection of the disease in the New York Skin and Cancer Hospital. He also spoke of the early diagnosis of the disease, and reported a case that at first looked like an exzema marginatum, but afterwards developed the characteristic tumors. Dr. Stelwagon, in closing, said that he found, in looking up the literature of the disease, some fifty or a hundred reported cases. It was exceptional for the disease to begin as tumors.

Dr. M. B. HARTZELL, of Philadelphia, then read a paper on

#### LYMPHANGIOMA CIRCUMSCRIPTUM, WITH REPORT OF A PECULIAR CASE.

This paper was discussed by Drs. Stelwagon and Bowen.

Dr. H. G. KLOTZ, of New York, followed with a paper:

#### REMARKS ON CARBUNCLE, WITH REPORT OF A PECULIAR CASE.

It was discussed by Dr. Bowen, who spoke of the remarkable paper by Dr. Warren, of Boston, describing the pathological anatomy of the disease.

Dr. C. W. ALLEN, of New York, then made some remarks on

#### ERYTHEMA ET NÆVUS NUCHÆ.

Dr. Zeisler thought it probable that erythema nuchæ was often due to pressure and rubbing. Drs. Fox, Duhring, Grindon and White also took part in the discussion.

Dr. M. GRINDON, of St. Louis, read a paper on

#### A CASE OF LICHEN RUBER.

Dr. Zeisler would be inclined to view the case as one of lichen planus. In this disease plantar and palmar thickenings are apt to form. Arsenic often cures these patients. Dr. S. Sherwell agreed with Dr. Zeisler in his diagnosis, though the case presented many exceptional features: one especially being the involvement of the nails. Dr. White believed the case to be one of lichen planus, and spoke of the uncertainty surrounding the whole question of the lichen group. Dr. Hyde said that he always found the polygonal outline of the papules to be well marked, something that does not seem to be familiar to the Germans and Freuch. Dr. Duhring agreed with the previous speakers in this diagnosis. The polygonal shape and umbilication are often wanting.

### Recent Literature.

#### *An Illustrated Encyclopædic Medical Dictionary.*

Being a dictionary of the technical terms used by writers on medicine and the collateral sciences, in the Latin, English, French and German Languages. By FRANK P. FOSTER, M.D., Editor of the New York Medical Journal, with eleven collaborators. Vols. I and II. With illustrations. New York: D. Appleton & Co. 1888 and 1890.

The title-page gives some idea of the scope of this work, and the promise of the title-page falls short of rather than exaggerates the performance of the pages between the covers. The publishers announce four volumes, and, if the other volumes are carried out with the fulness and thoroughness of the first two, it will be indeed a monumental work. Certainly there is no medical dictionary in the English language which can be compared to it. The paper and type are excellent. The size of the page is a quarto. There are 752 pages in the first volume and 1544 pages in the second. The number of subheadings under some of the long articles is almost bewildering. Under *abscess* there are 31 subheadings, under *abscess* 101, under *acid* 119, under *agaricus* 315, under *alcohol* 242, under *ammonium* 499, under *aqua* 565, under *artery* 1770, *bacillus* 259, *bath* 254, *bone* 411, *bursa* 321.

It is claimed, and its use indicates that the claim is just, that this dictionary is not a mere compilation from other medical dictionaries, but is founded on independent reading; the sources of information are given, and constant references to recent medical literature show an effort to keep pace with advances in medical science.

The full pronunciation of words is given. The illustrations are numerous, and, as a rule, excellent.

A review of such a work in a weekly journal is out of the question. A mere perfunctory notice is of little value. Our observations are the result of a good deal

of use of both volumes. We allow ourselves to express the hope that the work may be finished before long and within the proposed limits of four volumes, and that without lowering the standard of excellence reached in the volumes before us.

*A Guide to the Clinical Examination of the Urine.* By FARRINGTON H. WHIPPLE, A.B. (Harv.). Boston: Danrell & Upham. 1891.

Guides of this character have multiplied of late with great rapidity. This new addition to the list does not, in our opinion, fill any important gap in this branch of medical literature. In certain respects, it compares favorably with other works of the same class, and would be deserving of some praise were it not for the numerous inaccurate and inexact statements which it contains. It is stated for example, that when tyrosine is ingested by the healthy individual, his urea is increased by just so much nitrogen as was contained in the amount of tyrosine taken into the system; that the skilled observer is enabled, by the microscopic examination of blood, to determine from what animal the blood in question was derived; that the only means of distinguishing ordinary lactic acid and sarcocollactic acid lies in the fact that the latter forms salts with zinc and calcium; that calcic oxalate occurs only in acid urine, etc. Other examples might be given. Mr. Whipple has, we believe, made the mistake of rushing into print before acquiring that exact knowledge and experience which one should possess before attempting a work of this kind.

We presume that books of this character will be written as long as there is a demand for them; and this is likely to exist as long as there are students who desire to pass their examinations without possessing any real knowledge of the subject. We believe that examiners can most effectually check this demand by refusing to pass students whose books present evidences of this method of preparation.

W. B. H.

*Syllabus of the Obstetrical Lectures in the Medical Department of the University of Pennsylvania.*

By RICHARD C. NORRIS, A.M., M.D. Second Edition. Philadelphia: W. B. Saunders. 1891.

"The design of the book is to secure for the student a logical and consecutive outline of his work, and to aid him in classifying the knowledge he acquires in the lecture-room."

The syllabus first appeared in 1890; and the call for a second edition, eighteen months later, is a sufficient evidence of its usefulness. Some new material has been added, particularly in the chapters on Infant Feeding, Pathology of the Puerperium, Obstetrical Operation, and Dystocia. An index has also been prepared, and blank pages have been interleaved for additional notes. The book will doubtless find a continued usefulness in the student's hands.

*Essentials of Pathology and Morbid Anatomy.* By C. E. ARMAND SEMPLE, M.D. Philadelphia: W. B. Saunders. 1889.

"This is one of a series of question compends which are specially intended to assist students to put together the knowledge they have already acquired by attending lectures." If this is the case, the students who have to listen to lectures of which this book gives the essentials, have our pity. For it is simply a rehash of Green and other old English works on pathology, by a man who is a book-maker and not a pathologist.

THE BOSTON

## Medical and Surgical Journal.

THURSDAY, NOVEMBER 12, 1891.

*A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.*

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DANRELL & UPHAM,  
283 WASHINGTON STREET, BOSTON, MASS.

RECENT EXPERIMENTS WITH THE PNEUMOCOCCUS OF PNEUMONIA AND ITS TOXINE AND ANTITOXINE. THE POSSIBILITY OF CONFERRING IMMUNITY IN ANIMALS AND EVEN IN MAN.

G. AND F. KLEMPERER<sup>1</sup> have published a memoir in which are detailed some important recent experiments the practical outcome of which may possibly be of some real therapeutic importance.

The directing idea which guided these German investigators in their experiments was the following: It is known that in most cases pneumonia after having, during from five to seven days, caused grave general symptoms, terminates abruptly by crisis. In the space of a few hours, the temperature falls to its normal level and even below it, the pulse becomes slower and firmer, and the patient experiences a striking amendment. Now at this moment there has been little or no change in the state of the lungs which still remain infiltrated with fibrinous exudation, nor in the properties of the pneumococci which are found in great numbers in the sputa and retain all their virulence, as can easily be proved by inoculations of animals.

The pneumonic crisis, then, does not depend on any change in the state of the lungs or in the microbes which have caused the infection. To what, then, are we to attribute it? Only one explanation is possible; the crisis is due to the products of secretion of the pneumococcus, which, by their accumulation, modify at a given moment the soil on which the microbes develop.

In their experiments made on hares, the Klemperers early observed that any nutritive substance which had served as a culture medium for the pneumococci, even if it had been separated from the microbes by filtration, might confer on the animal immunity against the pneumonic infection. The power of this vaccine may be augmented, both in rapidity and intensity of action, by subjecting the liquid for two or three days to a

<sup>1</sup> Berlin klin. Wochens., August 21, 31, 1891.

temperature of 41° C., or during two or three hours to a temperature of 60° C.

They then obtained experimental proof that the blood-serum of a hare "vaccinated" against the pneumococcus, may cure the pneumonic infection; it suffices to inject this serum under the skin or into the veins of the infected animal. An intravenous injection of eight cubic centimetres of serum of an animal rendered refractory, practised twenty-four hours after the infection produces a gradual fall in the febrile temperature, and hastens the cure of the animal.

As will be seen, these experiments strikingly resemble those of Behring and Kitasato, who lately announced that the blood-serum of animals rendered refractory to tetanus and diphtheria is capable of curing other animals of these diseases.<sup>2</sup>

In another series of researches devoted to the study of the cause of the curative action of the serum of vaccinated animals, the German pathologists found that the pneumococcus when introduced into the body of an animal gives rise to the production of a *pneumotoxine* which may be isolated. This pneumotoxine produces a febrile reaction of several days' duration, after which they have noted in the fluids of the animal another substance, *anti-pneumotoxine*, which has the property of neutralizing pneumotoxine.

The blood-serum of an animal on which immunity has been conferred contains anti-pneumotoxine, and it is this which seems to forward the cure of the pneumonic infection. In the blood-serum of patients affected with fibrinous pneumonia, they have also found pneumotoxine and anti-pneumotoxine, the first, chiefly during the febrile period of the disease, the second, after the crisis. They claim to have cured the pneumonic infection in hares by injecting in these animals blood-serum taken from a pneumonic patient after the crisis.

After being assured by experiments made on themselves, that man may support with impunity and without any local and general reaction injections of the serum of animals rendered refractory to Fraenkel's diplococcus, the pathologists above mentioned ventured to experiment clinically, with therapeutic intent, on some patients affected with pneumonia. Although these trials covered only six patients, the result has been very encouraging. In fact, in all these patients, a hypodermic injection of four to six cubic centimetres of serum was followed at the end of from six to twelve hours by a considerable fall in the temperature with slowing of the pulse and respiration.

These experiments are especially noteworthy in that they so strikingly confirm the almost simultaneous and independent experiments of Emmerich and Fowitzky, who claim that they have conferred immunity on the hare by means of hypodermic injections of attenuated cultures of the pneumococcus; but this immunity, they say, is incomplete, and the extract of the organs of the animal has but an incomplete curative action. On hares infected by pneumococci, *per contra*, full im-

munity is obtained by intravenous injections of a culture having its entire virulence, but largely diluted. The liquid obtained by crushing and expression of the organs of an animal thus rendered refractory exercises on the pneumonic infection a sure curative action when it is injected under the skin into the abdominal cavity, and especially into the veins of the infected animal.

Large expectations are being entertained by many enthusiastic workers, that researches akin to those above noticed, now going on in many parts of the world — researches the inspiration to which came from Selmi, Gautier, Bouchard, and especially Koch — are destined to be very fruitful in therapeutic results, and that possibly the physician of the future, armed with his hypodermic syringe and his vial of "antitoxine" will find himself master of any and every infection. However, the disappointment experienced thus far in regard to tuberculin should cause us to entertain such expectations with a certain degree of caution and moderation.

#### DIURETIN IN GENITO-URINARY SURGERY.

"OUTSIDE of the usual complications liable to attend any cutting operation, the surgeon who deals with the genito-urinary tract has to contemplate, and, if possible, guard against, that other mysterious concomitant of operations upon the urethra and bladder, known under various names, and often called 'urinary fever.'"

All sorts of things have been done to prevent urinary fever, and most surgeons have some particular method or drug in which they have at least a slight confidence. But no method has met with perfect success; perhaps because the cause is not always the same, and the method needs to be varied with the cause; perhaps because the fever in question is the result of physical change which renders the individual incapable of enduring even a slight additional strain. While the pathology is imperfectly understood, it is still necessary to attempt, somewhat blindly, perhaps, to avert this unhappy occasional result of operations on the urinary tract.

In a paper read before the American Association of Andrology and Syphilology, at Washington, last September, and published in the *Medical News* of October 31st, last, Dr. Keyes suggests the use of diuretin as possibly likely to be available for this purpose. Diuretin is one of the new drugs which, as manufactured by E. Merck, of Darmstadt, is believed to contain fifty per cent. of theobromine, the other ingredient being salicylate of soda. It is said to be a free diuretic, pretty constant in its action, and its use at the Boston City Hospital has seemed to confirm that claim. According to Dr. Keyes, it does not irritate the stomach, bowels or kidneys, and does not depress a weak heart.

Dr. Keyes would probably be the first to point out the fact, that during the past year he has lost but one

<sup>2</sup> See vol. cxviii, No. 21.

urethral case, and that since using diuretin he has lost none, and could hardly expect to, if his former percentage is to be maintained. He expressly states that he does not assert that the drug has great value, or any value, but that it does no harm, and that since using it he has had no urinary fever proper—that is, there has never been a chill nor a suppression.

The operations done since he has begun to use diuretin have been mostly done on old men with damaged kidneys, all of whom recovered without chill or any tendency to suppression; and it is fair to imagine that the means used had something to do with it, and diuretin is the only new drug used.

"If it will prevent or even moderate urinary fever, it is a valuable drug." Dr. Keyes hopes to report a more extended experience with it next year, and his commendation will undoubtedly lead others to carry on control researches.

### TUBERCULOSIS OF THE SKIN.

THE three able papers on tuberculosis of the skin which appear in this issue of the JOURNAL form together a most complete study of this interesting subject. These papers were prepared at the request of the Council of the American Dermatological Association, for the purpose of introducing the subject for formal discussion at the recent meeting in Washington. Coming as it does after the interest aroused in the subject during the widespread trial of tuberculin, such a set of papers is of particular scientific and practical interest to the profession in general.

### MEDICAL NOTES.

THE EARTHQUAKE IN JAPAN. — It is estimated that the recent earthquake in Japan killed between six and seven thousand persons, and injured nine thousand more. Seventy-five thousand houses were totally destroyed.

JACK THE RIPPER. — The publicity given to the murders in the White Chapel district in London seem to have initiated similar murders in different parts of the world. The last one recorded is from Berlin during the last month.

THE CHOLERA AT DAMASCUS. — The ravages of cholera in Damascus show an alarming increase. The record for the last week in October shows 180 cases and 99 deaths. Owing to the prevalence of cholera, Hodeida is in nearly as bad a condition as Damascus, but at Aleppo the disease has subsided.

A VENEREAL CONGRESS. — A project is now under discussion by different boards of the Paris municipal government to establish an international congress to consider questions connected with prostitution and the limitation of venereal diseases. It is proposed to hold the congress in Paris, in 1893, and to invite medical men, lawyers, sanitary officials and political economists.

THE KEELEY CURE FOR DRUNKENNESS. — Mr. John F. Mines, known as "Felix Oldboy," who recently wrote an article which appeared in the *North American Review* for October, endorsing from personal experience the Keeley bichloride-of-gold cure for drunkenness, which article has been extensively noticed in the daily press, was arrested last week for being drunk, and taken to Blackwell's Island, where he died from the effects of alcohol.

DETECTION BY FINGER-MARKS. — M. Fargeot has made a communication to the Medical Society of Lyons relating to a discovery by means of which he can obtain an imprint of any hand that has touched a piece of paper, or of a foot that has trodden the floor of a room. The basis of his method consists in making visible by chemical means slight traces of perspiration or sebaceous deposit.

THE YANKEE MEDICAL STUDENT. — The *London Hospital Gazette* thinks that the Yankee medical student has not very much to be thankful for. First of all, the medical "diploma mills" turn out their thousands of ill-trained and indifferently educated youths to take part in the professional struggle for existence, and then no kind legislation has interfered for the purposes of restricting the practice of medicine to native graduates. And now Mr. McKinley has got passed a tariff, in virtue of which the tax on microscopes has been raised sixty per cent., so that an instrument which costs ninety dollars in Germany will at wholesale cost one hundred and fifty dollars in the States. This will hardly have the effect of stimulating microscopical work, and the cost will, of course, increase *pari passu* with the minuteness of the object to be magnified, seeing that the higher the power the greater the initial cost, and therefore the more crushing the protective duty.

COLOR COAST LIGHTS. — It would appear from the testimony in the Court of Inquiry on the stranding of the steamer *Dispatch*, that a lighthouse showing a fixed red light is objectionable on more grounds than the possibility of color-blindness of pilots. Apparently, the pilot mistook the fixed white light of Assateague for a fixed red light, and as the Winter-Quarter Shoal lightship was fixed red, he supposed that he saw the latter light. Everybody on board the steamer who saw the light, testified that the light appeared red to them.

A BELATED INSCRIPTION. — Dom Pedro, ex-emperor of Brazil, has recently presented three medals to Doctors Simmola, Charcot and Count de Mott-Maica. They have on one side the portrait of Dom Pedro, while on the other is the inscription: Presented to Dr. — by the Brazilian people out of gratitude for saving the precious life of their paternal emperor." While the medals were being prepared, his grateful subjects drove their "paternal emperor" from the country. They were finished a few weeks ago, and were forwarded to the ex-emperor who had ordered them.

## BOSTON.

**BEQUESTS TO PUBLIC INSTITUTIONS.**—By the will of the late Mrs. John F. Andrew, the following institutions will ultimately receive legacies: Massachusetts and Children's Hospitals, Society for the Prevention of Cruelty to Children, Kindergarten for the Blind, \$5,000 each; North End and South End Diet Kitchens, \$2,500 each.

## NEW YORK.

**MORTALITY OF THE CITY.**—There was a slight increase in the mortality of the city during the week ending October 31st, when 737 deaths were reported. This is an increase of 49 over the mortality of the preceding week, which was unusually small (688), and of 40 over the average of the corresponding week during the past five years. The deaths represent an annual death-rate of 22.65 to every 1,000 of the estimated population, against 21.15 for the preceding week, and 21.42 for the average of the corresponding week for the past five years. The principal increase was in the number of deaths from pneumonia, which amounted to 98, against 61 for the preceding week, and 81 for the average of the corresponding week for five years. Scarlet fever showed an increase of five, (the deaths numbering 15), and diphtheria an increase of 12 (32 deaths); although the mortality by the latter disease was six below the average of the past five years. There was also an increase of 12 in the deaths from diseases of the heart, which numbered 48.

**THE WATER-SUPPLY.**—Public-Works Commissioner Gilroy having become alarmed by the rapid decrease in the amount of water in the reserve storage reservoirs, has issued a warning to the public to prevent all possible waste. For three months the rainfall in the Croton water-shed has been less than was ever known during a like period, and there is danger that the water-supply will be exhausted within three weeks unless the greatest economy is observed in its use. Should heavy rains not occur very shortly, all sprinkling of the streets and other similar uses of Croton will be prohibited.

## Miscellany.

### SURGICAL TREATMENT OF PULMONARY CAVITIES.<sup>1</sup>

At the recent Congress of Tuberculosis, M. Poirier<sup>2</sup> read a paper on the surgical treatment of pulmonary cavities. He said the first case on record was accidental. In a duel fought in 1679, the sword of one of the combatants passed through his antagonist's lung and opened a pulmonary cavity. The surgeon utilized the wound for the direct treatment of the cavity, and the patient recovered. In conjunction with M. Jonnesco, M. Poirier has collected all the available statistics, of which the following is a summary:—Of 29 cases of incision of tuberculous cavities with resection of ribs, improvement took place in 15, cure resulted in four

(these cases must, according to M. Poirier, be taken "with every possible reserve"), in nine the result was negative, in one it was unknown. In 19 of the cases the disease was situated in the apex. M. Poirier, still with the co-operation of M. Jonnesco, has endeavored to simplify the method of operation so as to minimize the amount of traumatism. The following, according to them, is the best way of reaching the upper part of the lung. An incision is made with the thermo-cautery four centimetres below the sterno-costal notch from the middle line of the sternum outwards for nine centimetres in a direction parallel to the first intercostal space; in this way the pectoralis major, which is usually much thinned, is reached, and by enlarging one of the spaces between the fasciuli, the plane of the intercostal muscles is reached. This is divided and the pleura exposed. If there are no adhesions it is better to establish them before proceeding further, but if there is a cavity adhesions are always present. It is easy to "strike" the cavity through these adhesions, though a certain thickness of pulmonary tissue has often to be traversed for the purpose. As cavities are generally situated quite in the upper part of the lung, the first intercostal space is at a distinctly lower level than the cavity; the point of the instrument must therefore be carried from below upwards and from before backwards. When the cavity lies towards the back, the spinous process of the seventh cervical vertebra should be sought for; an incision is made outwards from this point towards the scapula; the trapezius and rhomboideus are divided, and the first intercostal space, which is much less wide than it is in front, is reached. Resection of rib may be necessary, but M. Poirier does not advise this. From experiments made on twenty dead bodies, he holds that in front resection of ribs is never called for.

### FLOATING HOSPITALS.

The Italian Society of the Red Cross has recently been conducting some elaborate experiments to test the working of floating hospitals. In countries where water communication is complete, well equipped hospitals on barges might be of very great service, especially in time of war.

The presidents of the Red Cross and Italian Rowing Club, with Captain Olivari of the Italian Navy, set themselves to the task, first by forming a floating hospital out of the barges employed on the main waterways for the transport of combustibles; then, having got their flotilla in working order, they launched it on the Lago Maggiore.<sup>1</sup> Passing thence by canal to Milan, it anchored at the Porta Ticinese, and was there visited by a large number of citizens. It is composed of three barges, two of them fitted up for the accommodation of the wounded, and the third for a pharmacy, a kitchen, and the necessary stores. Of the two hospital barges, one is set apart for wounded officers, the other for wounded soldiers of the line—the two containing each twenty-four beds at present, but capable of including comfortably thirty-six each. These beds are partly on the fracture-board system, partly supported on network of metal, and are all furnished with mattresses and pillows stuffed with *zostera marina* (dried seaweed), which has the twofold advantage of being non-combustible and antiseptic.

<sup>1</sup> British Medical Journal.

<sup>2</sup> Semaine Médicale, August 1st.

<sup>1</sup> Lancet, September 19th.

Every night requisite is conveniently at hand, and ventilation is secured by an ingenious canvas awning which gives passage to a continuous circulation of air while protecting the patient from draughts. The flotilla is lighted with oil lamps, and the barge reserved for the wounded officers has accommodation at the prow for the *personnel*, superior and inferior. The store barge consists of a dispensary, an *armamentarium-chirurgicum*, a provision magazine, with ice machines, and a spacious kitchen, capable of supplying 250 mouths. There is also a complete system for storing and keeping cool and pure a perennial water-supply—a system due to the Cavaliere Borroni, secretary to the Milanese Committee of the Red Cross. The flotilla is composed of nine barges in all: the three above described having been sent down to Milan for exhibition from the Lago Maggiore, while the remaining six are in dock at Arona, on the southern extremity of the lake. These barges are moved on the lakes by tugs, on the rivers by the current, on the canals by towing horses. From Milan the flotilla proceeded by canal to Pavia, and from Pavia down stream to Piacenza, at every station commanding the highest admiration. The experiment—the first of its kind ever made—is a worthy complement to the mountain ambulances of the Italian Red Cross Association.

#### HYGIENIC TREATMENT OF BRIGHT'S DISEASE.

CHIRON in *L'Union Médical*, June 23, gives a review of the different dietetic treatments of Bright's disease, and says, as a general rule, dark meats, such as wild fowls, and extracts of meat, such as Liebig's, should be avoided.<sup>1</sup> The chief danger in such foods is the toxic properties of the ptomaines they contain. In the periods when the disease is not active, white meats can be used, all condiments to be avoided. Some patients bear fish badly, but shell-fish can be used in moderation. Some patients bear milk and vegetable diet badly, and, in such, meats can be cautiously used, the urine being frequently examined to see that the albumen does not increase. Eggs are a disputed article; sometimes they agree well and sometimes badly. When, however, the digestive tract is in good condition they usually are well borne. Milk diet is, as a rule, the one best borne; it acts as a diuretic, diminishes the albumen, and increases the urea. Three and a half to four litres a day may be used. Certain patients cannot use an absolute milk diet, however, and in them a mixed diet is useful. A grape diet, skimmed milk or koumyss may be used with advantage. Most authors allow beer and a slight amount of light wines. In acute Bright's disease physical effort often increases the albuminuria. In this condition, and in the acute exacerbations of chronic nephritis, a patient should be in bed. In the chronic condition slight exercises are admissible, but where there is much polyuria or hypertrophy of the heart it is not to be permitted. Patient should avoid being chilled, and in winter should remain in a temperature as near as possible 75° to 80° and should wear flannel underclothing. The functions of the skin should be carefully looked after; baths, tepid and hot, followed by frictions and massage, are recommended by most authors, though Lecuclé and Talamon recommend the cold baths.

<sup>1</sup> University Medical Magazine, October.

#### MEMORIAL OF THE LATE DR. GEORGE H. LYMAN, FROM THE VISITING STAFF OF THE BOSTON CITY HOSPITAL.

At the regular meeting of the visiting staff of the Boston City Hospital, November 5, 1891, the following memorial was offered and adopted; and it was voted to send a copy to the family of Dr. Lyman, and also to the *Boston Medical and Surgical Journal*, for publication.

"Dr. Lyman became a member of the City Hospital Staff twenty years ago. To professional attainments of a high order he united a cheery brightness of disposition which made him a most welcome visitor to the sick-room, and nowhere was this more perceptible than in the hospital wards. No one who accompanied him on his rounds could fail to observe the gloom-dispelling power of his presence, and the smiling hopefulness of the patients who came under his influence. Kind-hearted by nature, the helpless suffering poor appealed to the strongest feelings of head and heart. He carried sunshine into the sick-room, and left it behind him.

It was not alone as the successful hospital physician, that Dr. Lyman deserves to be remembered. In the trying days of the Civil War he did brave and efficient work for his country, sacrificing very flattering professional prospects to enter the medical service of the United States Army. As Medical Inspector, he served throughout the entire period, and made a notable record in a field which allowed full scope to his active mind and tireless energy.

Dr. Lyman had been honored with the highest positions in the gift of the Massachusetts Medical Society. As President and Councillor he manifested the same lively interest in its affairs which he carried into every other duty of life, and with which we, his comrades, were so familiar.

A thoughtful writer, the treatment of his subject was always clear and interesting. His work on Ovariectomy should be especially noted, for the care and completeness of its preparation, and for the fulness of its statistics. His Boylston Prize Essay on "Non-Malignant Diseases of the Uterus" was also of a superior order. Other papers from his pen, such as his record of Army Experiences delivered before the Massachusetts Military Historical Society, excited much interest, and will be recalled with pleasure for their bright and entertaining style. His more serious historical papers have a high value for graphic style as well as for the information they contain.

A man of positive views and decided opinions, there was no mistaking his position when once his mind was made up. His side of the subject was advocated always with the energy and fearlessness of perfect conviction.

His life of usefulness was prolonged beyond the average. In another year he would have completed fifty years of professional life. His memory will remain dear to us as that of a faithful associate and true-hearted friend, whose influence will long stay with those who loved him.

JOHN G. BLAKE, M.D., *Committee*.

EDWARD J. FORSTER, M.D.,

*Secretary of the Visiting Staff.*

#### THERAPEUTIC NOTES.

TREATMENT OF DIPHTHERIA BY CYANIDE OF MERCURY.<sup>1</sup>—M. de Ruelle has obtained good results from the use of cyanide internally, recommended by Werner and Laëller, and as follows:—

R	Cyanide of mercury	gr. i.
	Alcohol	3 ij.
	Water	3 viij.
	A teaspoonful every hour.	

TONQUINOL, the new artificial musk, occurs as a snow-white crystalline powder with which needle-

<sup>1</sup> Medical Press, September 30th.

shaped crystals are interspersed.<sup>2</sup> The odor appears to be due to the presence of a nitro-terpene and nitro-sulpho-xytol. It is soluble in alcohol, water, fats, oils, ether, and chloroform. The alcoholic solution (1 in 50), on considerable dilution with water, is very agreeable in odor, and the perfume is not precipitated. At present tonquinol is sold by the manufacturers at the rate of one and one half pence per grain.

**DERMATITIS CAUSED BY RESORCIN.**—Dr. A. Ravogli<sup>3</sup> reports a series of cases in which the local application of resorcin was followed by dermatitis. The resorcin had been given as a salve, half a drachm to one ounce of vaseline, or as a wash of one and one half per cent.

**IODIDE OF POTASSIUM IN DIPHTHERIA.**—Zenkenko,<sup>4</sup> speaks highly of the treatment of diphtheria by iodide of potassium. In adults the drug should be given from five to eight grains every two to four hours, up to one-half to one drachm a day. In children, from one to fourteen years of age, single doses should range from a half to three grains. The administration should be continued until the appearance of iodism and an incipient separation of false membranes, which usually occurs on the second, third, or fourth day. As adjuvant means, he employed hourly gargling with a two or three per cent. boracic or salicylic acid lotion with glycerine and tincture of geranium or camphorated spirit; further inunctions of gray mercurial ointment (from one scruple to one drachm twice a day) were used for enlarged cervical and submaxillary glands, while stimulants, quinine, etc., were freely given.

## Correspondence.

A. D. 2000.

LIKE Bellamy's hero, I overdosed

With some seductive drug,  
And snoozed for more than a century  
Buried in cellar dug;  
Till an *ex post facto* Doctor man  
Into my quarters dug,  
And injected some hypnotic germs  
From a medical bungus.

He brushed off the dust of an hundred years,  
And gave me a cordial strong;  
"From all your surroundings it appears  
That you must have laid here long:  
You're clad in XIXth Century gear  
If my judgment is not wrong;  
'Tis well I found you; for my compeers  
Would have roasted you ere long.

"You see, we're working an arsenic mine.  
In the graveyards of Boston town;  
The corpses are solid with metal fine,  
And we reduce it down.

So solid it is that they often shine  
With crystals red, green and brown—  
Arsenic from sternum through to spine,  
From ossa calces to crown.

"Our histories tell, that, in days of yore,  
The populace all fell sick  
With illnesses which the doctors swore,  
Were due to arsenic.

Their glands, in a fashion unknown before,

Absorbed the poison quick;

From papered wall and carpeted floor,

They got it 'fast and thick.'

"From fabrics yellow, red, green or blue;

From clothing and furniture plush;

From whatever possessed a brilliant hue,

Not excepting a maiden's blush;

From the soot and smoke of the chimney flue;

From plain old Puritan mush;

From legumes, roots, tubers and canned goods, too;

From the fruit of vine and bush.

"For all of the neighboring country through

The farmers could be seen

Besprinkling whatever open they grew

With deadly Paris green;

It would kill the potato-bug, they knew,

Far better than kerosene,—

Gipsy-moths and flies and rose-bugs, too:

It killed them all off clean.

"The dust which was stirred by wind and sun

Bore to town a fresh supply,

And marketmen brought it in by the ton

For their customers to buy.

No wonder the mischief by arsenic done

Caused a great mortality!"

Here he paused and winked: "You know, my son,

There's arsenic in every *dye*."

C. F. C.

OCTOBER 26, 1891.

## RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, OCTOBER 24, 1891.

Cities.	Estimated popu- lation for 1890.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from				
				Infectious diseases.	Consump- tion.	Diarrhœal diseases.	Typhoid fever.	Diphtheria and croup.

#### OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOV- EMBER 7, 1891.

MANLY H. SIMONS, surgeon, ordered to U. S. S. "Mohican."  
FRANK DELBOIS, medical inspector, ordered to U. S. S. "Philadelphia."

T. WOOLVERTON, medical inspector, detached from U. S. S. "Philadelphia," and ordered before Retiring Board.

N. J. BLACKWOOD, assistant surgeon, detached from U. S. S. "Newark," and ordered to Navy Yard, League Island, Pa.

C. DEW. BROWNELL, assistant surgeon, detached from Navy Yard, League Island, and ordered to U. S. S. "Newark."

PHILIP LEACH, passed assistant surgeon, detached from the Naval Academy, and ordered to U. S. S. "Monocacy."

JOHN E. PAGE, assistant surgeon, detached from the U. S. R. S. "Independence," and to the U. S. S. "Iroquois."

JAMES G. FIELD, assistant surgeon, detached from Bureau of Medicine and Surgery, and placed on waiting orders.

#### THE AMERICAN PHARMACEUTICAL ASSOCIATION.

Membership is obtained only by election at the annual meeting. "Every pharmacist and druggist of good, moral and professional standing, whether in business on his own account, retired from business, or employed by another, and those teachers of pharmacy, chemistry and botany who may be especially interested in pharmacy and materia medica" are eligible for membership. For blank application and further information, address Dr. H. M. Whippley, 2729 Washington Avenue, St. Louis, Mo., Chairman of the Committee on Membership.

#### MIDWIFERY DEPARTMENT OF THE NEW YORK POST- GRADUATE MEDICAL SCHOOL.

Mrs. C. F. Huntington has given the Directors of the Post-Graduate Medical School, a sum sufficient to defray the expenses of the Midwifery Department for one year. Professor von Kandelohr will have charge of this Department, at No. 543 1st 13th Street, where instruction in obstetrics will be given to graduates in medicine only.

#### EXAMINATION FOR INTERNES, CARNEY HOSPITAL.

The regular examinations for the position of house-officer at the Carney Hospital for next year will be held at 188 Marlborough St., on Tuesday, December 1st, at 3.30 P. M. Application must be made before November 28th to the secretary, Dr. J. J. Minot.

#### SOCIETY NOTICES.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT.—The Section for Clinical Medicine, Pathology and Hygiene will meet at 19 Boylston Place, on Wednesday, November 18th, at 7.45 o'clock.

Reports of Committees: On "The Condition of the Streets of Boston," and on "The Need of an Emergency Hospital in the Business District."

Papers: Dr. H. F. Vickery, "Unsuspected Heart Disease" (Drs. E. N. Whittier and F. C. Shattuck will open the discussion); Dr. Malcolm Storer, "A Successful Case of Double Ovariotomy."

ALBERT N. BLODGETT, M.D., Sec'y., 390 Boylston St.  
E. G. CUTLER, M.D., Chairman.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.—The next meeting of this Society will be held at Albany, February 2, 3 and 4, 1892. Drs. Seneca D. Powell, No. 12 West 40th Street, New York, James D. Spencer, of Watertown, and Franklin Townsend, No. 2 Park Place, Albany, have been appointed the Business Committee. Any communications regarding papers or any matter pertaining to the business of the Society which should properly come before the Business Committee should be addressed to Dr. Seneca D. Powell, 12 West 40th Street, New York City. F. C. CURTIS, Secretary.

A. WALTER SUITER, President.

THREE CASES OF COMPOUND FRACTURE OF THE PATELLA, IN WHICH THE BONES WERE WIRED WITH GOOD RESULTS.<sup>1</sup>

BY A. T. CABOT, A.M., M.D., BOSTON.

THESE cases are reported as a contribution to the statistics of this operation.

It is the writer's feeling that in simple fractures of the patella the added risks of an opening into the joint are so great that the best treatment is by apparatus, with bandaging so applied as to bring the fragments as close together as possible. In such cases an operation may be required after the leg has recovered if the fragments are so far apart that the limb is practically useless. Ordinarily, however, the ligamentous union gives a strong and useful leg even when the fragments are separated by a considerable interval.

In compound fractures of the patella where we already have an opening into the joint the question is quite a different one, and the operation of wiring seems to be demanded in every case, for not only is the chance of a useful joint increased by wiring the bone, but we have also the opportunity of clearing the joint of blood and fragments of bone, and with dependent drainage provided for, the chance of a healing by first intention without suppuration is greatly increased.

In all of the cases reported silver wire was used, and this wire was cut off short and buried by being pressed down firmly against the surface of the bone. In none of the cases did the wire give any trouble.

CASE I. John B., a large, vigorous man of twenty-nine, entered the Massachusetts General Hospital, July 15, 1887, with a compound comminuted fracture of the right patella.

Under ether, the opening was enlarged by a transverse incision over the joint. The middle portion of the bone was shattered into small pieces which lay about loose in the joint, and were thoroughly removed.

The fragments remaining attached to the quadriceps tendon and the ligamentum patellæ were evened off with a saw, so that smooth surfaces could be approximated, and then attached to each other by two wires.

Dependent drainage was provided by tubes low down on the sides of the joint, and the leg was placed on a posterior wire splint.

Healing took place by first intention, and he left the hospital on September 13th, with a stiff bandage on the leg.

In November he was going about with no bandage and with good motion in the knee, and in December his knee was so well and strong that he could go upstairs two steps at a time. In the latter part of December he made a misstep coming down, and refractured the patella, the separation occurring, as nearly as could be made out, along the line of union of the old fracture.

He re-entered the hospital on December 26th, in Dr. Porter's service, and the case was treated as a simple fracture by apparatus.

He left the hospital on January 28th, with a stiff bandage. When this was taken off two months later, the patella was found firmly united by what appeared to be bony union. One of the wires could be felt, but had caused no trouble, and the vertical diameter of the

patella was one-half an inch greater than on the well side.

The leg gradually became strong, and the motion in the joint was restored until in May, 1891, the patient could bend the knee considerably past a right angle, and ordinary walking was not interfered with. The patella was perfectly movable.

CASE II. J. B., a heavy man of fifty-one, fell from a roof on October 22, 1888, sustaining a simple comminuted fracture of the left patella, while in the right leg he suffered a compound comminuted fracture of the patella, and a compound fracture of the thigh about four inches above the knee-joint.

The opening into the right knee-joint was enlarged by a transverse incision.

The bone was so thoroughly comminuted that after the loose pieces had been removed, there were left two small fragments attached above to the quadriceps tendon, and one still smaller wedge-shaped piece on the ligament below.

A wire was passed from side to side through the two fragments above, and the lower fragments being too small to give holding-ground, the wire was passed through the ligament just below it.

When this wire was tightened, it drew the little wedge of bone below up between the two upper fragments and held it firmly.

Dependent drainage was provided by tubes on the sides of the joint and the leg was treated on a posterior wire splint as in the former case, with the addition of extension to the thigh by a modified Buck's apparatus.

The wounds in the legs healed by first intention, in spite of the fact that a severe facial erysipelas developed about a fortnight after the injury.

At the end of two months the patella was firmly united, and the knee had a good degree of mobility. Unfortunately, the thigh did not unite, and in consequence of this fact the whole leg was encased in plaster.

In the summer of 1890, hearing that this patient's leg was useless on account of the ununited fracture of the thigh, I sent for him, and he re-entered the hospital; under ether I cut down upon the ends of the bone, and dovetailed them so that they fitted together and were held in position by the tension of the muscles.

This operation was followed tardily by union of the femur, but the long confinement of the leg in apparatus and stiff bandages had led to a stiff knee.

Now on May 5, 1891, the right patella which was wired is fixed to the front of the femur. There is very slight motion between the femur and tibia.

On the left leg the patella is so closely united that no interval can be felt between the fragments, and there would seem to be bony union were it not that by grasping the upper and lower portions of the bone firmly a little lateral motion can be detected. This knee has good motion and is strong.

The good motion that was found in the right knee at the end of two months when the patella was firmly united, shows beyond a doubt that this knee would have been at least as good as the other if passive motion could have been begun at that time.

Unfortunately, the long subsequent confinement of the leg (two years) finally caused a fixation of the patella, and stiffness of the joint.

CASE III. James M., a strong man of twenty-seven, entered the Massachusetts General Hospital

<sup>1</sup> Reported at the meeting of the Surgical Section of the Suffolk District Medical Society, May 6, 1891.

August 3, 1890. He had just fallen from a freight car, striking the ground upon his knees, and had sustained a compound comminuted fracture of the left patella.

He was at once etherized. The opening over the patella was enlarged by a long incision transverse to the joint. The blood and loose fragments were removed from the joint, and there then remained one large fragment attached to the quadriceps above, and two small fragments attached to the ligamentum patellæ below. Two wires were introduced, each of them attached one of the lower fragments to the large upper fragment. Drainage-tubes were introduced low down on the sides of the joint, and the wound was stitched together. Recovery was uninterrupted. The stitches were all taken out on the eighth day, and the wound was perfectly healed by first intention.

At the end of three weeks the patient left the hospital on crutches, with the left leg encased in plaster. This plaster bandage was removed about two months later, at which time the bone was found to be firmly united, and the patient was allowed to begin passive motions for the restoration of the functions of the joint.

May 6, 1891, the following condition existed. The wired patella seemed to be firmly united by bony union, and equalled the patella on the well knee in size. It was freely movable. The leg was strong, and the knee would bend almost to a right angle. Steady improvement was still going on in the usefulness of the joint.

In all of these cases the result as far as apposition of the fragments and restoration of the bone was concerned, was better than can ordinarily be obtained in simple fractures of the patella which are treated without operation. As far as can be judged at this time the fragments have united in all three of these cases by bony union, and what is more, the patella which has resulted in each case is three or four times as large as the fragments of which it was composed. In each instance the middle part of the patella was broken into a number of loose fragments that had to be removed from the joint cavity, leaving comparatively small fragments to be attached together, yet the patella in each case has been restored to its full size.

In the first and third cases the fragments of bone were sufficiently large to allow of putting the wire through from the anterior surface of the upper fragment to the surface of the fracture, then entering by the fractured surface of the lower fragment to bring it out on the anterior surface of that. Thus the wire did not enter or encroach on the joint cavity. The important point being to have the wire come out on corresponding points on the broken surfaces; it is well to drill the holes from these surfaces to the anterior surface of the bone, and in this way a very exact adjustment can be made.

In Case II, the small size of the pieces of bone made some other method of wiring necessary, and the circular wire running through the different fragments and gathering them together as by a purse-string, answered admirably. By this method, too, the wire can be tried, as was done in this case, through the ligament below a fragment that is too small to hold it.

The method of wiring by carrying a circular wire around the fragments was first practised in 1865 by Dr. Samuel Cabot in one of the earliest cases on record in which a wire was used for uniting the frag-

ments of a patella. There was much suppuration in this case, done before the days of aseptic surgery, and the patient died five months after the operation. No autopsy could be obtained, but there was every evidence of a bony union between the fragments.

The second accident that happened to Case I shows that care in the avoidance of unusual strain is important even for some time after the joint appears to have recovered full strength and usefulness.

Passive motion may be begun much earlier with a wired patella than with one that is treated as a simple fracture. In the latter case the ligamentous union must have time to become firm or it will be stretched when a strain is brought upon it; when the patella is wired, however, we may expect bony union at the end of seven or eight weeks, and after this passive motion may be begun. It will be safer for some time, even after this, to wear a splint or stiff bandage when going about in order to avoid the chance of a sudden strain.

## TWO CASES OF AMPUTATION AT THE HIP-JOINT.<sup>1</sup>

BY J. COLLINS WARREN, M.D.

THESE cases are reported for the purpose of illustrating the success which may attend an operation of this severity in advanced tubercular disease of the bone with many of the complications which attend it. In one case primary, in the other secondary amputation was performed.

CASE I. D. L., eighteen years old, had had disease of the right hip for ten years. He had been able to get about on crutches until two months before entrance into hospital, when the knee-joint, which had troubled him for some time, suppurated, and he had since been confined to his bed. The abscess discharged through a sinus in the popliteal space; and at the time of entrance to the hospital (November 4, 1890), the joint was completely disorganized, and moved freely in all directions, causing great pain on the slightest motion. The inner condyle was protruding through the popliteal space.

When I first saw the patient he was on a stretcher in the accident-room, having just arrived and appeared to be suffering greatly and in a state of great delirium. Emaciation was extreme. I found no difficulty in making the forefinger and thumb of my hand meet around the thigh of the healthy limb. A more careful examination later disclosed numerous sinuses discharging from the neighborhood of the hip-joint. The lungs were in a healthy condition. There was increased dulness in the regions of the liver and the spleen. An examination of the urine showed the presence of one-quarter per cent. of albumen and hyaline and fatty casts. The pulse was fairly strong, and the patient showed great pluck and determination to go through any operation that would relieve him of his sufferings. On consultation it was decided that amputation should be performed below the trochanters, and, if the shock was not too great, that the head of the bone should be removed also.

The operation was performed November 8th. A strong rubber tubing was passed around the thigh at the groin and held above the trochanter by means of a retractor. Amputation was done by the circular

<sup>1</sup> Reported at the Meeting of the Surgical Section of the Suffolk District Medical Society, May 6, 1891.

method as high up as possible, and the vessels having been secured, a vertical incision was made over the trochanter, and the head of the bone with a portion of the shaft was dissected from its socket. A small portion of the periosteum of the shaft was saved. The joint proved to be healthy, but a sequestrum occupied the region of the trochanters. The shock from the operation was comparatively slight; and before the patient left the amphitheatre he exclaimed, in answer to a question, that he felt "good." The wound healed partly by first intention and partly by granulation.

On December 10th the record states that the patient was about on crutches, and that the urine had cleared up and the liver dulness had greatly decreased.

On December 31st the patient was discharged with a small sinus about one-inch deep on the outer surface of the stump. He had gained greatly in weight and was in excellent condition.

CASE II. E. T. F., a tall and emaciated young man about nineteen years old, entered the hospital October 23, 1890, with hip-disease of the right limb, of fourteen years' duration. The femur was dislocated backwards and strongly adducted. The right leg was very much shorter, greatly atrophied and nearly useless, although formerly he had been able to touch the tips of the toes to the ground. There was an abundant discharge of pus from several sinuses on the thigh and hip, and a marked evening rise of temperature. His general condition was otherwise good, and the urine was normal. On November 15th an examination under ether showed that the head and greater portion of the trochanter had disappeared. The end of the bone was exposed and about three inches of the shaft was excised. A temporary improvement followed the operation, but the discharge of pus soon became as abundant as ever, and the "pus temperature" re-established itself. The limb was accordingly removed on December 20th, and an attempt made to lay open the sinuses about the acetabulum; but the shock of the operation rendered any prolonged dissection inadvisable. The patient rallied well from the operation, but the flow of pus continued.

On February 5th an examination was made under ether, and a large pus cavity in the buttock was laid open, and an attempt was made to drain the acetabulum.

Shortly after this I was able to pass a probe through the acetabulum into the pelvis, and it was then found that pressure on the right iliac fossa was followed by an abundant discharge of pus. By straining, the patient could force a jet of pus through this sinus.

On February 23d the whole stump was laid open by a long incision; and the acetabulum being freely exposed, a sinus was seen communicating with the interior of the pelvis. This was enlarged with the chisel so that two fingers would be passed easily through the opening, and the probe was felt presenting in the right iliac fossa. The cavity was thoroughly washed out with a weak solution of corrosive sublimate, and two large-sized drainage-tubes were inserted, a third being placed beside them to drain the external wound. From this time on the patient gained strength rapidly, and the discharge of pus diminished.

On March 19th he used crutches for the first time, and left the hospital March 25th.

May 6th. At an interview with the boy's father to-day, I learn that after leaving the hospital there

was a rise of temperature with increased discharge from the wound, but that the temperature is now nearly normal, and only about a tablespoonful of pus comes from the four tubes that are at present in the wound. He is able to walk on crutches and to make his way about the house. He has gained greatly in strength and flesh, and the prospects of complete recovery are now good.

Case I. I am able to show you this evening. You observe that the patient is in perfect health, and no sinus of any kind is to be found in the stump. My thumb and fore-finger extend only half way around his thigh. The disappearance of all symptoms of amyloid degeneration of the liver, kidneys and spleen, which seemed to be well marked before the operation, is, perhaps, the most interesting feature of this case.

## PROGNOSIS IN POTT'S DISEASE OF THE SPINE.<sup>1</sup>

BY SAMUEL KETCH, M.D., NEW YORK,  
*Chairman Orthopedic Section of the New York Academy of Medicine;  
Clinical Professor of Orthopedic Surgery, Woman's Medical College, New York, etc.*

In making a prognosis regarding the result in a case of Pott's disease, the surgeon has many different factors to take into consideration. We will succinctly treat of these from the following standpoints: (1) location, (2) age of the patient, (3) etiology, (4) complications, (5) thoroughness of treatment.

Clinically the vertebra, the seat of an osteitis, regarded from the standpoint of prognosis, may be considered as follows: the superior region, from the first cervical to the third dorsal vertebra, inclusive; the middle, from the fourth dorsal to the tenth; and the inferior region, from the eleventh dorsal to the fifth lumbar vertebra, inclusive.

As a matter of clinical experience it is commonly asserted that of these regions, more cures are affected in the superior and inferior regions and in a shorter space of time, than in the middle portion of the spine.

In order to have some definite statistics concerning regional prognosis, I have taken 75 cured cases, through the kindness of Dr. Newton M. Shaffer, from the case-books of the New York Orthopedic Dispensary and Hospital, and divided them equally amongst the different regions. These cases, I would state, were not selected ones, but taken as they presented in the regular order of admission. I have analyzed them from the following standpoints: (1) sex; (2) age at which they presented for treatment; (3) etiology; (4) duration from time of beginning of treatment, until the patient was discharged cured; (5) complications arising in the different regions during treatment.

We shall first consider the superior region.

Of the 25 cases, 10 occurred in males, 15 in females; a proportion on which no argument can be based to show that either sex is peculiarly liable to disease in this region.

As to the age at which the patients presented with disease in this area, I found that the youngest was one and a half years, the oldest seventeen years of age; five were from one to five years of age; thirteen were from five to ten years, and seven over ten years old.

Regarding as we do that spondylitis is essentially a

<sup>1</sup> Read before the American Orthopedic Association at Washington, September 24, 1891.

disease of childhood, although not absolutely so, this would show that during this period, that is, from one to ten years, 18 cases presented, or about 72 per cent. of the total number. From clinical observation I should be of the opinion that disease in the superior region occurs at an earlier age than in the middle or inferior areas. It is worthy of note also, that with these cases we are not always in the position to discover how long the disease existed before presenting for treatment, questions as to this point eliciting the most vague and oftentimes unreasonable replies. Thus, I have seen large kyphoses, which the parents stated had only existed for a short time. Again, in attempting to arrive at some conclusions regarding the etiology of spondylitis in the superior area, the answer given to the question as to causation, "as stated by patients or parents," was almost invariably, "I do not know." This was also true of the other areas, where no leading questions were asked concerning falls or injuries; the peculiarity in the latter respect being that most all the patients could furnish a history of a fall at one period or another.

In attempting to give the relation of etiology to prognosis, I shall consider the total number of cases; and of the 75 cases included in this paper, no definite cause was assigned in 68. Seven cases, three in the superior region, two in the middle, and two in the inferior region, give unmistakable histories of traumatism. In all of these seven cases, the time occupied in the treatment was much less than in the others, bearing out the fact, that simple traumatic cases are, as a rule, more favorable from the standpoint of prognosis. I found that in 45 of the 68 cases, or about 60 per cent., some evidence of hereditary tubercular predisposition could be found, either on the side of the father or mother, phthisis being the most frequent disease. This bears out researches of Jaffé, Gibney and Taylor, regarding the tubercular origin of the majority of cases of Pott's disease. The influence of etiology on prognosis, is therefore most important in estimating the outcome in any given case.

The duration of time from the beginning of treatment until the patient was discharged cured, showed that in the superior or cervical area  $26\frac{2}{3}$  months as the average time occupied in gaining this result. The shortest time taken in any given case was three months, the longest eight years. This also included the time of observation after the apparatus was removed, and while the patient was still regarded as liable to relapse. It must also be remembered that these cases were treated in a public institution, that they did not receive the best home care, and that in many the treatment could not be carried out as regularly and as faithfully as in private practice; all factors which would materially influence the prognosis. Of the complications most liable to happen in the course of Pott's disease, namely, abscesses and paraplegia, of the total number analyzed, this region gave but one case with abscess and one with paraplegia.

In the middle region fifteen cases occurred in males and ten in females. The time at which the patients presented for treatment, showed the youngest recorded age as twelve months, the oldest thirty two years. Ten were from one to five years of age; nine from five to ten; and six from ten to thirty-two years. The average time occupied in obtaining a cure in this area, shows an average of  $61\frac{1}{2}$  months. The shortest time in any case being one year, the longest eighteen

years. Eight cases in this region were complicated with abscesses and but two with paraplegia.

The occurrence of but three cases of paraplegia in the superior and middle regions, is, I hardly think, a fair estimate of the liability of the superior and middle areas of the spine to the occurrence of this complication, as clinically the proportion is much larger than appears from these cases, and these regions may be truly called the "paraplegic regions of the spine." Two of the cases in the middle area were also complicated by a coexisting hip-joint disease.

In the inferior region twelve cases occurred in males, and thirteen in females. The youngest case recorded as presenting for treatment was one year old, the oldest twenty-six years. Thirteen were from one to five years of age; nine from five to ten; and three above ten years. The average time occupied in obtaining a cure in this region was  $47\frac{1}{2}$  months. The shortest time in any individual case was six months, the longest nine years and four months. Ten cases had abscesses and but one paraplegia in this region. Other complications recorded were two cases of morbus coxarius, one of these cases being a double hip-joint disease.

It would hardly be commensurate with a paper on the prognosis of such a chronic, painful and deforming disease as the one under discussion, to dismiss the subject without a brief allusion to the questions of deformity and mortality.

It is an unfortunate fact that the majority of cases brought to the orthopedic surgeon have already advanced to the stage of deformity; and one of the first questions asked, is, as to the disappearance of the lump. Regarding its absolute disappearance, I am convinced that very few cases have this fortunate conclusion. We are certainly in the position to prognosticate a smaller amount of deformity in the cervical and lumbar regions, but our art is hardly yet advanced to that point where we can promise a complete recession.

That this does occur at times there can be no doubt, and in rare instances we all witness it, but as stated before this Association, in a paper read at the last annual meeting, "Some of the marvellous cases of supposed organic kyphoses the result of caries, were, in reality, puzzling cases of posterior rachitic curvature." I am convinced, however, that the prognosis of deformity will be much better in proportion to the time at which we are enabled to begin treatment, and that in this, as in other deforming diseases, much is still to be done in the way of prophylaxis, by rendering the diagnosis so clear that patients with incipient disease will be placed under treatment at the earliest opportunity.

In regard to mortality it is my belief, that, with improved methods of treatment and better facilities for carrying these out, both in public and private practice, the percentage of deaths from Pott's disease *per se* has been materially decreased. Indeed, it is rather with the complications or sequelae of the disease that mortality occurs.

The influence of thorough mechanical treatment on the prevention of abscess and paraplegia, will be brought before the Association by another member. I am convinced, however, that the carrying out of mechanical treatment in every detail exercises a very decided influence in preventing these serious complications of Pott's disease, not only reducing the mortal-

ity but rendering the eventual prognosis more favorable.

As to the statistics regarding mortality, we are already in possession of sufficient bearing on this point: Jaffé, 22 deaths in 82 cases; Mohr, seven deaths in 72 cases; and Billroth and Menzel, 23 deaths in 61 cases.

A point of some importance in prognosis is the known fact of the tendency of some cases to spontaneous recovery. If this were to apply to any particular class of cases, it would pertain to those of traumatic origin, in cases without hereditary tubercular taint. We are, however, in possession of no other means of differentiating these at the beginning from cases which pursue the ordinary chronic course.

Another fact largely influencing ultimate prognosis, is the opportunity to be able to carry out treatment over a long period. The statistics here compiled show that in no portion of the spine can we produce uniformly rapid cures, and I should urgently protest against the strong tendency towards the early removal of apparatus, as the relapsed cases only frequently show the folly of this step.

A résumé of the more important points evolved by this analysis would show that in 75 cases 37 were males, 38 females; that 28 cases presented from one to five years of age, 3 cases from five to ten years, 16 above ten years old; that the average time of treatment in obtaining a cure was  $26\frac{1}{2}$  months in the superior region,  $64\frac{1}{2}$  months in the middle region,  $47\frac{1}{2}$  in the inferior region; that, as a complication, abscess was most frequent in the middle and inferior areas, nearly fifty per cent., developing there in the course of the disease; that paraplegia may be looked for more frequently in the superior and middle areas, rarely in the inferior.

#### TORSION; WITH DESCRIPTION OF AN AUTOMATIC FORCEPS FOR RAPID TORSION.<sup>1</sup>

BY F. M. BRIGGS, M.D.,  
Surgeon to the Boston Dispensary.

ALTHOUGH torsion has several distinct advantages over any other method of treating hæmorrhage, and although with certain limitations it is both safe and practicable, it has never found general favor as a hæmostatic measure and is rarely made use of.

The method is a very ancient one, having been recognized and practiced in the first and second centuries. In the early part of the present century it came into use in France, but after having been tried for a while, was finally abandoned, as being unsafe when applied to large arteries.

Warren<sup>2</sup> states that torsion was brought to the notice of and was used by Velpéau in 1826; that it was also practiced by Amussat, who, in 1829, presented a paper on the subject to the Academy of France.

Ashhurst<sup>3</sup> says that in this year (1829) it was successfully used in Germany; but was followed by several failures in France, and it was referred to Duyppuyten for thorough investigation. His report was unfavorable to torsion except in the case of small arteries. After this the method went out of use, but was revived and practiced by Syme.

Bryant<sup>4</sup> speaks of it very highly. In an experience of nine years, upon vessels of all sizes, he has never had a mishap, and he believes it to be the most perfect physiological method at command for the treatment of hæmorrhage.

Warren,<sup>5</sup> speaking of its physiological value, refers to the experiments of Kocher, who concludes that: "Torsion enjoys with acutorsion and acupressure the great advantage of favoring a rapid coagulation, and also has its own special advantage of producing a much more intimate union between the thrombus and the vessel wall . . . these advantages are especially true of illimited torsion; when properly done, it is the ideal for small arteries."

Holmes,<sup>6</sup> although believing it safe, prefers the carbolized ligature, and thinks, that "even the most experienced operator will find that it takes a long time to close all the vessels in a large stump by torsion . . . and that much more handling of the parts is required."

Gross<sup>7</sup> is doubtful as to its safety upon large arteries, and Ashhurst<sup>8</sup> is strongly opposed to it, being of the opinion that "the only truly efficacious means of arresting the hæmorrhage from large arteries are compression and ligation."

No method of treatment is justifiable which does not offer the greatest possible security against the occurrence of secondary hæmorrhage. Such an accident is too serious to admit of taking any chances, and, with opinion thus divided, it would certainly seem better to use the ligature upon such vessels as the femoral, carotid and axillary, and to confine the use of torsion to the smaller vessels, where the question of safety can be disregarded. But, with this limitation, there is still a very wide field for its use; for, where the femoral is tied once, numbers of ligatures are being put upon vessels small enough to come strictly within the limits of safe torsion.

Twisting is done in one of two ways. In limited torsion the artery is seized with one pair of forceps, drawn out of its bed, grasped at its deepest point by a second pair, and the portion between the two forceps is then twisted four to six times.

In illimited torsion the artery is seized and twisted with one pair of forceps, without the aid of the second pair—the fixed point against which the twisting is done being found in the tissues in which the vessel is embedded.

After having tried illimited torsion upon small vessels, some time ago, it seemed to me, that probably one reason why it is not in more common use, is because, with our present forceps and method of performing it, torsion is a slow and clumsy proceeding; and it occurred to me, that if an instrument could be made which would twist quickly and effectively, and which, at the same time could be easily handled, that such an instrument might be found useful as a general hæmostatic for the smaller vessels.

My first models had a box of gearing wheels connected with a rod, to which the forceps were attached; by turning a small handle the wheels were set in motion, and the forceps made to revolve rapidly. I abandoned this model for its use required both hands, and it needed too much manipulation. These difficul-

<sup>8</sup> International Encyclopedia of Surgery.

ties have been overcome in the model as shown in the accompanying cut. This instrument has the very great advantage of being wholly under the control of one hand, and its mechanism is such, that by a simple up-and-down motion of the box (*g*) over the spiral rod (*e*) the vessel is seized, twisted and released.

Inspection of the cut will show the principle upon which it works, and this can be made clear by a few words of explanation. The instrument is taken with the thumb in the ring at the top, and the first and second fingers in the rings on the box (*g*). The hand is opened and the box pushed firmly down. The arms (*f*) drop over and grasp the ring (*c*), carry it down, and the forceps spring open (as is shown in the smaller drawing).

It is then ready for use. The forceps are placed over the vessel and the box (*g*) is drawn up. The arms (*f*) pull up the ring (*c*) which presses against the upper ends of the forceps and closes them over the vessel. The arms then strike the projection at (*d*), spread open, and leave the ring (*c*) *in situ*, holding the forceps firmly locked. The forceps cannot be again opened until this ring has been pushed down. Torsion is performed by pulling up the box (*g*) three or four times, over the whole length of the spiral rod, that is to say, by closing and opening the hand three or four times. Drawing it up three times gives six full twists, which ought to be sufficient. When the torsion is completed, the vessel is released by again pushing the box firmly down. The arms (*f*) push down the ring (*c*) and the forceps spring open.

This whole performance, namely, seizing the vessel, twisting and releasing it, is perfectly simple and very rapid, as it takes only three to four seconds.

This instrument checks the bleeding, not only from those vessels which have a distinct vessel wall and can be easily isolated, but also from small bleeding points, provided they are seated in tissue which will allow them to be twisted. But in old cicatricial tissue, in the skin, etc., they are bound down, and tend to break off instead of twisting.

Regarding the instrument, it is to be noted that there is no backward rotation. When the box (*g*) is drawn up, the forceps revolve. When it is pushed down, the forceps are stationary. Of course, if the motion were reversed, the vessel would be untwisted, and the torsion of no value. A small ratchet in the thumb piece allows the spiral rod to turn in one direction, but acts as a brake to prevent it from turning in the opposite direction. The box (*g*) contains a brass cylinder, fitting closely upon the grooves of the spiral rod, and toothed at its lower end. When the box is drawn up the teeth engage, making a solid body of the box and cylinder, and the spiral rod revolves; but when the box is pushed down the teeth

disengage, and the brass cylinder revolves around the rod which is then stationary.

It is also to be noted that the opening and closing of the forceps is wholly automatic. This mechanism is plainly shown in the cut and needs no explanation.

The forceps (*a*) are the ordinary hæmostatics with short upper ends. They are pivoted on a pin at (*b*) and are held open by a small spring, which cannot be seen in the drawing but which is just below this pivot.

The instrument is cleaned as follows: The pin at (*b*) which pivots the forceps is fastened to a plate. By turning this plate half round, the pin can be pulled out and the whole instrument taken apart. There is no point which cannot be easily reached and thoroughly cleaned. The forceps pull out of the shaft, the ring (*c*) slides off, the shaft is taken off the spiral rod, the box (*g*) removed, and by unscrewing the cap from its upper end, the brass cylinder can be taken out. The arms (*f*) can be taken off, and, if desired, the thumb ring can be unscrewed. To allow of thorough cleanliness the number of different parts has been purposely made large. Some difficulty may be found in putting it together again. To do this: First, put the brass cylinder, with the toothed end *down*, into the box (*g*) screw the cap on, and slide the box upon the spiral rod; second, put the shaft on the rod; third, put the ring (*c*) on the shaft; fourth, push the forceps into place; fifth, re-insert the pin (*b*) and turn the plate to which it is attached back into position.

When taken apart it is complicated. When put together and ready for use, it is not complicated. It is simple, compact and strong.

The instrument has been made for me by Tiemann & Co., of New York. Mr. L. G. Pfarre, of this firm, has taken great pains in the details of its construction, which was very difficult on account of the tendency to friction between the various parts.

It is intended for illimited torsion, and can be safely used upon all vessels cut in any operation:

- (1) Upon the forearm and hand.
- (2) Upon the leg below the upper third and the foot.
- (3) About the head and face.
- (4) Upon the surface of the body generally, as for the removal of tumors, for the radical cure of hernia, for plastics, etc.; and this class includes a very large proportion of all operations performed.

In comparing torsion with the ligature, it can be stated that every ligature is a foreign body in the wound at the time it is applied. Until recently, ligatures were treated as foreign bodies, and were removed at a later period of the case. We now know that this is not necessary; that an aseptic ligature can be left in the wound, and that it ought to be taken care of in the healing process, being either absorbed or becoming encysted.

Notwithstanding this great advance in surgical detail, it would certainly be better if all wounds could be closed without containing any knots of foreign material; there is always the possibility that ligatures apparently aseptic, are not so; and, if aseptic, the wound has an extra amount of work in disposing of them. Where only one or two ligatures are applied, this work may be insignificant, but where any number are necessary, it must become an appreciable factor.

In torsion, however, no foreign substance is left in the wound. After torsion by this rapid method, the twisted ends are seen as small, compact knots, and

Three-fifths of actual size.

these are apparently no greater hindrance to healing than are the ends of the vessels which project beyond the ligatures after tying.

Asepsis is more certain than with any form of ligature. The only object which comes in contact with the wound is the forceps; while in tying, in addition to the forceps, we have the ligature itself and the hands of the operator or assistant in tightening the knot.

Primary union ought to be facilitated, for it is obvious that where ligatures are aseptic and therefore innocuous, still, there can be no union of the cut surfaces at the points where they are applied until the foreign element has been removed by absorption or by encapsulation; and this must take a longer time than is needed in disposing of the small knots left by this instrument.

The writer wishes to express his indebtedness to Dr. J. C. Warren, to whom he is under very great obligations for his kindness in giving an opportunity to use the instrument, and to test the method at a number of his operations at the Massachusetts General Hospital, last March. At these trials, which were upon cases where no large trunks were involved, bleeding was successfully and permanently checked.

Several defects in the instrument, which prevented it from working smoothly, were made apparent, and the experience obtained through this courtesy on the part of Dr. Warren, has been of the greatest assistance in perfecting these defects.

### Clinical Department.

#### FRAGMENTS OF GLASS REMOVED FROM THE POPLITEAL SPACE WHERE THEY HAD LODGED FOR OVER THREE YEARS.<sup>1</sup>

BY G. H. MONKS, M.D., BOSTON.

IN February, 1888, F. M., a laborer thirty years old, met with an accident in which his left leg was thrust forcibly through a window-pane, the fragments of broken glass causing a long lacerated wound in the upper part of his calf. He put himself under medical care, and eventually the wound healed. He was not obliged to stop working for any length of time, though he always had an "uncomfortable feeling" at the seat of the wound. Even after the wound healed the uncomfortable feeling persisted, and he was not able to fully straighten his knee or to get his heel squarely to the ground when walking. This left knee being always slightly bent was much in his way when he worked, and it was also especially exposed, on account of its prominence, to injury. While the man was at work one day, about a year and a half after the original injury, a barrel of ashes fell upon this knee. A synovitis followed, but under treatment this soon disappeared.

For the last three weeks the patient has been more troubled than ever by stiffness and pain in the knee-joint, and by the uncomfortable feeling at the seat of the old wound, as well as by his not being able to put his heel to the ground.

Finally, in the Out-Patient Department of the Carney Hospital he was carefully examined by Dr. W. M. Conant, who made the diagnosis of foreign body

in the popliteal space and sent the patient for operation into the hospital, where he came under my care in the surgical wards.

At the lowest portion of the popliteal space there was a long scar in the median line. Above this and slightly to the outside of the median line a large, firm, resistant body could be felt. A long and deep incision made in the axis of the limb over the centre of this body revealed a mass of cicatricial tissue in the popliteal space. On incising this a large fragment of glass was found. It was lodged so firmly in position that many incisions through the hardened tissue were necessary to free it. Three smaller fragments also were found deep down in the tissues just behind the head of the tibia. A sharp corner of the large fragment projected through the joint-capsule posteriorly and lay within the joint-cavity just below the external condyle of the femur. The figure shows the pieces of glass in their actual size.

The thickness of the glass was one-eighth inch. The large piece was two inches long and one inch broad at its broadest part. There was no sign whatever of pus in the wound, but an abundance of fibrous tissue. The wound was sewed up, and at the end of the fifth day the stitches were removed. The wound had united firmly by first intention, and on the ninth day after the operation the patient walked home, being able to get his heel squarely on the ground.

He was seen on the street some weeks later and he declared that his left leg was then as sound as his right one.

*Remarks.* The interest in this case centres principally in the fact that such large fragments of glass can be carried for so long a time within the body and cause so little trouble in the way of inflammation, pain, etc. The inability to straighten the knee and to get the heel to the ground was the principal source of annoyance to the patient, but this was a purely mechanical matter.

It is said that the domestic pets of the world carry at least thirty per cent. of the common contagious diseases from house to house.

# A CASE OF FRACTURE OF THE PATELLA, WITH A NEW METHOD OF WIRING.

BY THOMAS KITTREDGE, M.D., SALEM, MASS.

B. U., fifty-four years of age, fell on a slippery sidewalk on the 17th of January, 1891, landing upon his back without, as far as he knows, striking his knee. He was much surprised to find that he could not stand upon his right leg, and to feel a sharp projection above the knee. He was taken to the Salem Hospital, where a transverse fracture of the patella was found. The fragments were easily brought together, and held by a figure-of-eight bandage, the leg being put upon a ham splint. At the end of eight weeks, union seeming firm, with very slight separation of the fragments, he was discharged, at his own request, with the admonition that he should use the greatest care. One month later, having returned to his post as janitor of a building, while going down stairs, he felt his knee giving way, and was precipitated to the landing below. He was put to bed for two weeks, the joint being swollen and painful. At the end of that time thinking, as he says, that it was all well, he got up and was in the act of pulling on his trousers (standing upon his right leg), when he was suddenly thrown to the floor by his knee giving way.

He was brought to the hospital, where I found a separation of the fragments of nearly four inches. I told him that any attempt at repair without an operation, was out of the question, and advised wiring the fragments, to which he consented. The operation was done on the 18th of May, under irrigation with an aqueous solution of bichloride of mercury 1-6000. The knee was but little swollen, and free from heat and pain.

An incision was made transversely across the joint from one condyle to the other, passing through the fibrous capsule between the fragments of the bone and into the joint-cavity, which was found full of fluid and old blood-clots. There was no connection between the fragments, the broken ligamentous band lying between. The joint, including the upper synovial pouch, was carefully washed out, and all debris removed. The fractured surface of each fragment was sawed off with a fine saw, and the ragged edges of the capsule trimmed with scissors. The joint was quickly washed out again, and the sawed surfaces brought into close apposition, and held there while two holes, on each side of the fracture, were drilled to the depth of half an inch. These holes converged a little towards the opposite ones, and were about three-eighths of an inch from the sawed edge. Into these holes two stout wire rivets, a little less than an inch long, with prongs bent at right angles, three-eighths

of an inch long, were placed. My object in beveling the holes being to have the wires more securely held in place, and less likely to slip out, but as it was necessary to elevate the outer edges of the patella to do this, and as it proved to be somewhat difficult, another time I should bore the holes perpendicularly and make the rivets bulb-pointed or serrated, and a little smaller than the drill, so that callous would be thrown out about them and hold them securely in place. After the rivets were driven in, the periosteum, which had previously been carefully turned up and pushed back, was brought down and stitched together with fine catgut. A continuous catgut suture was put in the fibrous capsule, and the skin united with silver wire. Rubber drainage-tubes were placed in the angles of the wound, the leg was put upon a ham splint, and the usual antiseptic dressing applied to the knee. The dressing was removed at the end of six days, and the wound, with the exception of the openings for the drainage-tubes, found to have healed by first intention. The tubes were removed and these openings speedily closed by granulation. The leg was kept upon a ham splint for eight weeks, when a silicate of soda bandage was applied, and the patient allowed to go about on crutches.

The present condition, nearly six months after the operation, is as follows: The joint is in nearly a normal condition, there is but little swelling or enlargement, the surface of the patella is smooth, the line of fracture cannot be felt, there is no movement of the fragments, and the movements of the joint are unimpaired. If not a bony union, there is a very close ligamentous one, and the rivets are still in place.

The wire used was of galvanized iron, but another time I should use copper or platinized silver, as less likely to corrode. The advantages of this method over the ordinary way of wiring the patella, it seems to me are: closer apposition of the fragments, thereby assuring a stronger union, with less danger of the wires tearing out, greater expedition in doing the operation, a smaller external wound, less disturbance of the joint, while the wires on the upper surface lie flatter than wires that have been twisted together and then bent down.

The chief danger from the operation of wiring the patella lies in the suppuration that is likely to follow opening of the joint. By this method, provided there is not great laceration about the joint, the deeper parts need not be disturbed, and consequently the danger of suppuration will be less. In cases where the periosteum or the fibrous capsule is not wholly torn through, the fragments of the bone might be pressed together and the rivets applied *through* the capsule or periosteum.

I believe that if the proper antiseptic precautions are faithfully observed, wiring of the patella is not only justifiable, but is the only treatment that offers a satisfactory result in cases where the fragments have been long separated, cannot be approximated, or a ligamentous union having formed, separation again takes place.

THE AMERICAN HOG. — Another instance is reported in which the American hog has been unjustly maligned by jealous German officials. A more complete investigation in the case of a hog filled with trichinae showed that he was of German birth, and that his flesh had been eaten raw.

## New Instruments.

### A NEW FORM OF SPLINT FOR THE THUMB.<sup>1</sup>

BY JOEL E. GOLDTHWAIT, M.D., BOSTON.

This splint will be found useful in securing fixation of the thumb, and possesses the special advantage of not restricting the motions of the wrist or fingers, and hence can be worn without serious inconvenience to one's business. It can be used in any conditions where fixation is demanded, and is especially useful in the lesser injuries, such as "base-ball thumb," where the more bulky outside splints would not be tolerated.

FIG. 1.

FIG. 2.

It is made of tin, and can be cut out by any one in a very few minutes. The pattern of the splint is

shown in Figure 2, and the following dimensions may be found convenient; they are the measurements for a splint for the average adult hand.

The base (*a b*) should be seven inches long and one and one-half inches wide. The thumb-piece (*c*) should be two inches long, and one and three-quarter inches wide in the widest part. The tongue (*d*) is a narrow strip one-quarter of an inch wide and four inches long.

The thumb-piece and base are bent, at their point of juncture, to an acute angle, while the tongue is bent around the base piece and holds the two parts rigid. The wings (*a* and *b*) are bent to clasp the hand while the sides of the thumb-piece are rolled up to form a trough for the thumb to rest in. It is held in place by two strips of adhesive plaster, one around the thumb and the other around the hand. No padding is necessary, but to prevent chafing the edges of the splint should be bound with adhesive plaster.

## Medical Progress.

### RECENT PROGRESS IN ANATOMY.

BY THOMAS DWIGHT, M.D.

#### OSSIFICATION IN THE HEAD OF THE HUMERUS AT BIRTH.<sup>1</sup>

DR. HERBERT R. SPENCER has examined the head of the humerus on both sides in 180 fetuses, many of which, however, were immature. He suggests that we may assume that those weighing six pounds or more were mature, of course, however, without a view to statistics. He found a bony nucleus in 14 cases, usually of the size of a "No. 6" shot. Of the fetuses 40 weighed seven pounds or more, and nine of these had the epiphysis. Dr. Spencer states that all the 14 in which bone was found were probably mature, and all of them had a bony centre at the lower end of the femur. The conclusions which he draws are necessarily guarded. They are:

"First, that a centre of ossification is not rarely met with in the head of the humerus of mature fetuses at the time of birth.

"Second, that in large fetuses (that is, weighing seven pounds or more) the centre is commonly observed—in my own cases, in at least 22.5 per cent. This frequent occurrence in large still-born children would seem to have some medico-legal importance."

Investigations of this kind deserve great encouragement. The statements concerning ossification seem to be to a great extent copied from one book to another. Some of them are utterly wrong, and pretty nearly the whole subject needs revision.

#### THE DIFFERENCE OF THE HEIGHT STANDING AND SITTING.<sup>2</sup>

Professor Riccardi, of Modena, reports observations on 1,185 persons of all ages, of whom 584 were males and 601 females. The sitting height is almost always greater than half the total height. Thus it exceeds it in 95.4 per cent., equals it in 2.7 per cent., and falls below it in 1.9 per cent. In adult males the sitting height is 52 per cent., and in females 53.2 per cent. of the standing height, showing that in women the trunk

<sup>1</sup> Journal of Anatomy and Physiology, xsv, July, 1901.

<sup>2</sup> We are indebted for this to an abstract by Dr. Collignon in l'Anthropologie, 1891, tome II, No. 1.

<sup>1</sup> Shown at the meeting of the Surgical Section of the Suffolk District Medical Society, May 6, 1891.

with the head is relatively longer than in man. In children the proportion is still greater. There is at first no difference in the sexes. The adult proportions appear at the age of thirteen or fourteen. It is shown that of two persons of the same age (and presumably of the same sex) the taller one has relatively the shorter body; which is simply saying that tall persons have relatively longer legs.

#### THE DIFFERENCE OF HEIGHT IN THE UPRIGHT AND RECLUMBENT POSITIONS.<sup>3</sup>

This is an old question which M. Ch. Fére has studied again. He examined 165 persons (the sex is not mentioned), dividing them into groups. The mean difference seems to be rather less than one centimetre. We are surprised to find that neither the height nor the age seems to have much influence. The greatest difference observed was three centimetres.

#### THE SHAPE AND SIZE OF THE TRACHEA.<sup>4</sup>

Dr. Lejars has published a very suggestive paper, which deserves serious consideration. While it may be questioned whether his method is sufficiently accurate to permit his results to be accepted, it is hard to doubt that he has called attention to an important fact generally overlooked. Indeed, the fact itself was pointed out by Dr. Nicaise (in the *Revue de Médecine*, November, 1889), from whose work Dr. Lejars quotes. Nicaise found that if the front of the trachea of a dog had a window made in it, the mucous membrane of the posterior wall projected forwards as a longitudinal fold, and that the ends of the (so-called) rings were in contact. This, at least, was the condition of the animal when calm, but if it cried out the trachea dilated and the membranous fold disappeared. Speaking, apparently, of man, Dr. Nicaise continues: "In the normal condition when the breathing is calm, the windpipe is in contraction during both stages of respiration. The ends of the rings are in contact and the borders of the rings touch. The membranous portion is drawn together, and the mucous membrane over it makes a slight projection into the interior of the tube. In forced respiration, in crying, sighing, singing, etc., the trachea dilates and lengthens during expiration,<sup>5</sup> the larynx rising; the trachea contracts and shortens during inspiration,<sup>6</sup> and the larynx descends." It is needless to say that this contraction is the work of the involuntary muscular fibres of the windpipe and of its elastic tissue. The fact which Lejars insists upon is that the dead windpipe, which has been measured and described, is a very different thing from the living one. So far, good. Now, how are we to measure the living one, or, at least, estimate its measurements? Dr. Lejars's plan is to put the ends of the rings in contact, allow the posterior mucous membrane to fall forward in a fold, and then trace the outline and measure the diameters. We do not know any better method, except perhaps in cases when it might be possible to freeze the body during the *rigor mortis*, but we feel that this one is hardly satisfactory. In spite of Nicaise's statements one is inclined to ask, Is it certain that the ends of the rings are actually touching? Lejars seems to think it is so; we will follow him. We do so the more readily that though we question the accuracy of the method we do not doubt the general correctness of

his views. The following table shows the averages of his measurements of 11 windpipes taken both in the dead and the living position.

	Dead.	Living.
First ring . . . .	16.7 mm.	12. mm.
Third ring . . . .	16.8 mm.	11.7 mm.
Sixth ring . . . .	17.5 mm.	11.6 mm.
Ninth ring . . . .	18. mm.	11.8 mm.

A glance shows that the difference is considerable. There are two types of windpipes, those with a large and broad and those with a narrow posterior membranous portion. It is evident that the former will show the greatest differences. Moreover, this membranous portion grows broader from above downwards, and this accounts for a peculiar difference between the dead and the living trachea. The former grows larger from above downwards; the latter has its greatest size above. It is to be expected that in older persons the difference will be less, as with advancing age the cartilages lose their elasticity and the muscles their power.

In further support of his views Lejars refers to the experience of surgeons who have found the introduction of the tube after tracheotomy impeded by the prominence of the posterior mucous membrane.

#### THE SUSPENSORY APPARATUS OF THE PLEURA.<sup>6</sup>

The closure of the top of the chest has been variously described; some authorities finding a fibrous septum which has even been compared to the diaphragm, others denying any such structure. Dr. Sébilleau denies it entirely. He finds, however, several structures, of which there are many varieties, muscular or fibrous, passing from the spine and ribs to the top of the pleura, which together constitute the suspensory apparatus. He describes it as formed by two bundles, more or less mixed below, but quite distinct above. One is superficial, superior and internal; the other deep, inferior and external. The superficial one is usually muscular, but sometimes fibrous. About as thick as one of the *lumbricales* of the hand, but varying a good deal, it arises from the transverse process of the seventh cervical vertebra, and sometimes from the sixth also, descends and spreads out on the top of the pleura, is attached to it, and then goes to the first rib. Sometimes the muscle is very small, sometimes it is replaced by fibrous tissue.

The deeper part seems to be always fibrous. It arises externally to the one described from the first rib and divides into an outer and an inner branch. The inner branch runs under the superficial one, mixing with it, and going to the pleura, sometimes also to the first rib. The outer division is weaker than the inner, its outer fibres run to the inner border of the first rib, but all are attached to the top of the pleura. He describes also an occasional band passing from the bodies of the lower cervical or the upper dorsal vertebra to the top of the pleura.

He very properly considers the former more important structures as belonging to the system of the *scaleni*. It is not necessary to consider various details brought out by Sébilleau, whose careful dissections deserve high praise. The structure, however, is not as new as he supposes. The writer begs to present an extract from his book entitled, "Frozen Sections of a Child," published ten years ago.

"According to Zuckerkandl<sup>7</sup> the (subclavian) artery

<sup>3</sup> Bull. Acad. de la Société de Biologie, 1891, No. 27.

<sup>4</sup> Revue de Médecine, Paris, April, 1891, No. 1.

<sup>5</sup> That these two facts have been inadvertently transposed.—T. D.

<sup>6</sup> Bull. Soc. Anat., Paris, 5th Série, tome VI, July, 1891.

<sup>7</sup> Zeitschrift für Anatomie und Entwicklungsgeologie, Bd. II.

and the plexus are generally separated by the scalenus minimus (long known as an anomaly), which arises from the transverse processes of the sixth and seventh cervical vertebrae, or the latter only, and from the upper border of the first rib. It runs to be inserted into the same rib between the structures just mentioned, but it is attached also to the top of the pleura. Its chief purpose apparently is to strengthen and tighten the latter. Sometimes the place of the muscle is taken by fibrous bands, which, indeed, had been observed by Sibson."

#### AN ALLEGED NEW LIGAMENT OF THE HIP.<sup>8</sup>

Dr. Bellini, dissecting at Clamart, thinks he has discovered an undescribed ligament of the hip-joint. He begins by pointing out that, as a rule, those which have received names are after all only thickenings of the capsule. His new ligament is more distinct, being sometimes more or less detached from the capsule. He finds it constantly, and states that his researches have been verified by Dr. Scibileau. We give his account in his own words: "This new ligament of the hip is a strong one. In most cases, as I have said, it is free in its course from the fibrous capsule; but in some subjects it is seen to mingle with it in a part of its extent, near its lower third. Its place is then marked by a strong thickening of the capsule.

"It arises above the cotyloid border, from the lower edge of the reflected tendon of the *rectus femoris*, runs from above downwards, and from behind forwards towards the anterior inner border of the great trochanter, below and a little in front of the tendon of the *gluteus minimus*, with which it tends to fuse. In dissecting the joint one often destroys it in removing this tendon of the *gluteus minimus*, which is, no doubt, the reason why it has remained unknown to anatomists till now.

"It is triangular and broad in its upper portion, then it becomes round as far as its insertion to the great trochanter." He goes on to say that this ligament is sometimes so strong that it cannot be pulled out. He proposes to call it *ligament tendino trochantericum*.

In Morris's excellent "Anatomy of the Joints," we find the following passage in which we incline to think the same structure is referred to, though the descriptions do not quite agree. "Between the ilio- and the ischio-femoral bands, the capsule is stout and strong, and with it here, near the acetabulum, is incorporated the long tendon of the rectus; while at the femoral end the longitudinal fibres composing it are concentrated to a narrow insertion into the ridge on the front border of the trochanter, close to the *gluteus minimus*. It is this portion of the capsule which is greatly strengthened by a strong fasciculus of fibres passing from the under surface of the *gluteus minimus* to the capsule half-way between the iliac and femoral attachments; while further forwards, and near to the outer edge of the ilio-femoral ligament, a tendinous band, closely blended with the surface of the capsule, stretches between the upper extremity of the tendon of origin of the vastus externus, and the long tendon of the rectus." This is a point of anatomy to which the writer of this Report gave particular attention a few years ago. Though he has seen the arrangement described by Morris he was not able to believe it constant. He finds it very difficult to accept Bellini's views.

<sup>8</sup> Bull. Société Anatomique, Paris, 1891.

#### NEW SUBDIVISIONS OF THE ABDOMINAL CAVITY.<sup>9</sup>

Henke remarks that we are used to think of the abdomen as distended, but that we get more correct ideas of its topography and of its natural subdivisions by considering it as flat; by taking as normal the condition it presents in a thin, young subject. He would divide its cavity into four parts, distinguished from each other by three narrow spaces through which they communicate. The highest chamber is in the concavity of the diaphragm separated by a narrow transverse cleft at the level of the umbilicus, from the other three. It contains the liver, spleen, pancreas, duodenum, and the whole of the stomach when not abnormally distended. It contains also the transverse colon, though its middle portion is pretty close to the boundary. The remainder of the abdomen is divided into a middle portion, continuous with the cavity of the pelvis, and two lateral ones which are separated from it by narrowings opposite the psoas muscles. These lateral portions correspond therefore to the iliac regions, and the lower portions of what is commonly called the lumbar regions. The transverse narrowing between the three lower and the one upper chamber is, indeed, very narrow when the abdomen is flat. The most interesting part of the paper treats of the position taken by the folds of small intestines. He believes that its upper portion lies in the left lower space with the folds arranged in the main transversely, and the lower portion in the middle space with the folds disposed more vertically. He states that often (referring, we suppose, to thin subjects), on opening the abdomen one needs only to feel a little about the left psoas between the folds that cover it, to be able to separate them naturally into two masses, one to the left, the other to the right, which join only at the lower part. The left mass is the upper part in transverse folds, and the right the lower in vertical ones.

While we incline to believe that there is some foundation for these views, it must be remembered that the question is not an easy one to settle. One or two irregular folds may confuse a plan that is, in the main, simple; and again, any one with a "view" is in danger of letting his imagination delude him. It is to be hoped that further studies will be made.

#### THE RELATION OF THE INTERNAL EPIGASTRIC ARTERY TO THE ABDOMINAL WALL.

Dr. Rudolf Trzebiecky,<sup>10</sup> the author of this paper, had the misfortune to puncture either this artery, or a considerable branch of it, in tapping the abdomen. He chose the spot advised by Monro, the middle of a line from the navel to the anterior superior spine of the ilium. This induced him to investigate the question of the fitness of this spot. He examined in all 36 bodies. In a series of 23 bodies in which the abdomen was flat, that is, not distended, he found the artery running over the point in question in five, in one of them on both sides. In three cases the artery was less than one centimetre distant. In seven cases (in two on both sides) a muscular branch would have been in the way. The next series comprised 10 cases, the abdomen was prominent from ascites or fat. In two of these the artery crossed the point of election (once on both sides), and once was only one-half centi-

<sup>9</sup> Archiv. für Anat. et Physiol.; Anat. Abtheil., 1891, heft. 2 and 3.

<sup>10</sup> Zur Wahl der Einstichstelle bei der Paracentese der Bauchhöhle, Arch. für Klin. Chirurgie, Bd. XII.

metre away from it. Moreover, in six a large branch crossed the spot.

The author experimented on three subjects, to find out what effect the distention of the abdomen would have on the position of Mourou's point. This was done by first marking the point, and then injecting water through the navel. He found that the point was displaced a little downwards and more or less outwards. He does not, however, attach much importance to this. He concludes that in most cases this point is a safe one, but still that in a considerable number either the main vessel or a branch is endangered. As a rule, the artery crosses the line from the umbilicus to the spine at the junction of its middle and inner third. The position of the artery is rarely the same on both sides. As the artery runs in the sheath of the *rectus*, its course, to a great degree, depends on that muscle. Still the relation is not a constant one, for in some cases the artery lays nearer the middle line on the side on which the artery was most displaced outwards. The place of origin of the epigastric from the iliac seems to have no influence on its subsequent course.

Dr. Trzebicki is inclined, on anatomical grounds, to advise the *linea alba* for paracentesis. He points out, however, that it is important to keep strictly to the median line, as a strong anomalous branch may be found close beside it, which has been wounded with a fatal result. It is, however, very uncommon. If the *linea alba* be not chosen, he advised the outer half of the line from the navel to the iliac spine.

#### THE BRANCHES OF THE THYROID AXIS.<sup>11</sup>

Among the questions sent out a year ago by the committee of Collective Investigation of the British Anatomical Society, the first was as to the "mode of origin of the following vessels, usually described as branches of the thyroid axis, namely, inferior thyroid, suprascapular, ascending cervical and transverse cervical arteries." We do not see why the posterior scapular was not included in the question, for, as the answers show, it could not be kept out of it, and, moreover, from its tendency to spring from the third part of the subclavian, its origin is of practical interest to the surgeon. No less than 541 answers were received. They are tabulated by an ingenious system of diagrams. We can mention only the types which occurred most frequently.

(1) In 160 cases (29 per cent.) the thyroid axis gave off at once the suprascapular, then the transverse cervical, which divided into the superficial cervical and the posterior scapular, and finally the inferior thyroid giving off the little ascending cervical. This is the arrangement given as normal in Quain and Gray.

(2) In 121 cases (22 per cent.) there is no transverse cervical, but the superficial cervical which represents it arises at almost the same point as the suprascapular. The posterior scapula arises from the third of the subclavian.

(3) This type is almost the same as the first. It occurred 18 times (8 per cent.). The difference is that the axis divides almost at once into its three branches, instead of giving off the suprascapular and the transverse cervical successively.

(4) This was found 39 times (7.1 per cent.). There is no transverse cervical. The suprascapular gives off the superficial cervical. The posterior scapular springs from the third part of the subclavian. We have in-

terpreted these diagrams so as to call the little ascending cervical a branch of the inferior thyroid. It would be possible, as is sometimes done, to describe the continuation of the axis as dividing into the inferior thyroid and the ascending cervical. There are 32 other diagrams, but as none of them represent as many as five per cent. of the cases, we pass over them. These diagrams are very clear, and bear witness to the great industry of the committee.

## Reports of Societies.

### AMERICAN PUBLIC HEALTH ASSOCIATION.

NINETEENTH ANNUAL MEETING, held in Kansas City, Mo., October 20-23, 1891.

#### FIRST DAY—MORNING SESSION.

The Association convened in the auditorium of the Warder Grand Opera House, and was called to order at 10 A. M. by the President, FREDERICK MONTIZAMBERT, M.D. F.R.C.S., D.C.L., Quebec.

Prayer was offered by the Rev. SAMUEL N. NEEL.

After considerable preliminary work, the reading of papers was proceeded with.

Dr. D. McDONALD, of Kansas City, read a paper on

#### THE CAUSE AND PREVENTION OF INFANT MORTALITY,

in which he gave statistics showing that infant mortality soon after birth was twenty per cent. One of the principal causes was exposure to a low temperature—a chilly room soon after birth. He had been present when it was necessary to wear an overcoat in a room where a newly-born child was exposed to bathing. Forcing sleep by soothing syrups to overcome the effects of this exposure was another evil. Another trouble was the forcing of food, such as crackers, water and whiskey into the young, inert stomach of the newly-born child. The mother who refused to nurse her child from selfish reasons deserved the censure of the community. Statistics show that in the first year the infant mortality, when the child is fed by artificial food, is fifty per cent. With natural food the mortality was but ten per cent. The best artificial food was pure cow's milk. Sterilization by chemical process was not thoroughly a success because vital principles cannot be supplied by chemical process, but sterilization was preferable to impure milk.

No starchy substance could be digested in the infant stomach. Starchy infant food is converted by the chemical processes of the stomach first into sugar, then alcohol, and then acetic acid. No sensible farmer would attempt to feed a calf hay. Hay is the natural food for a cow as much as solid food is for man. Improper dressing, such as thin clothes, was also a prolific source of infant disease.

Prof. W. W. DANIELS, of Madison, Wis., thought that no one should be allowed to sell milk in cities unless he put his dairy establishment under the control of the sanitary authorities.

#### GLANDERS IN MAN

was the subject of a paper by Dr. JOSEPH SHARP, of Kansas City, Mo.

He classed glanders with acute infectious diseases, such as tuberculosis. The especial feature of the pa-

per was a report of a case which occurred in his practice, and in which he pointed out the difficulty of diagnosis in this obscure disease, and gave an outline of the methods for microscopic examination together with the best methods of cultivating the bacillus of glanders. The paper recommended that, for preventing glanders, persons who came in contact with horses having open sores or discharges from the nose, should disinfect the hand with a solution containing a tablespoonful of equal parts of glycerine and carbolic acid in a quart of hot water, or ten grains of corrosive sublimate in a quart of water. In his report of the fatal case which he had treated, that of a painter, who became inoculated through a sore on the hand while handling an afflicted horse, the speaker aroused much interest.

DR. PAUL PAQUIN, of Battle Creek, Mich., in the discussion, reported a collection of seventeen cases of glanders in man, which he had collected in the State of Missouri while living there. As an instance of the virulence of the poison, Dr. Paquin spoke of one man who, driving behind an affected horse, was struck in the eye by a spray from the beast's nostrils, a case of glanders developing rapidly and terminating in the man's death.

CHIEF JUSTICE HORTON, of Kansas, read a paper on

#### THE NECESSITY FOR MORE STRINGENT LEGISLATION TO REPRESS EMPIRICISM.

He said that the mountebank of the nineteenth century, with brazen face and clarion voice, travels the length and breadth of the land proclaiming himself as "Diamond Dick," "Indian Bill," or by some other equally euphous and ambiguous title, as he asserts his skill and disposes of his wares. It might not be justifiable homicide to compel him to swallow his own darksome nostrums, but the present laws are insufficient for his repression and, however beside himself he may become, we can hardly hope that he will so far forget his villainy as to administer unto himself that which he so recklessly deals out to others.

To protect the public, the American Public Health Association should recommend the enactment of statutes excluding from the medical profession those who are not competent by learning, skill and experience to practice, and punishing by imprisonment any who violate the provisions. No one should be permitted to practice medicine or engage in surgery unless authorized to do so by a competent board of Government or State examiners.

DR. R. HARVEY REED, of Mansfield, O., said it was no easy matter for the medical profession to eradicate quacks or pretended medical men. Whenever the subject of quackery was brought before the legislature, the profession had to contend with two prominent factors, namely, the quack themselves, who furnished large quantities of money, and, second, the general press of the country. Why the press? Because the quacks paid the newspapers more money for advertising than the regular medical profession, consequently the press aided the quacks in trying to down the law.

The next paper read was on

#### WATER-SUPPLY AND PUBLIC HEALTH.

by MR. ALLEN HAZEN, of Lawrence, Mass., in which the author dwelt principally upon the typhoid fever and cholera germs which infect impure water. Typhoid fever and cholera bacteria are taken into the

system through food and drink. Pure water is therefore a necessity. If water is absolutely free from sewage it can be depended upon as being comparatively pure, although many waters not polluted by sewage have been known to breed disease. Flowing streams will partially purify themselves. Reservoirs and long channels, where water flows and becomes aerated, will not always purify it. Some system of filtration is therefore imperative, and the question to be decided is the best means of filtration. Several systems were described, but all were said to be more or less defective.

At the close of this paper, DR. HENRY B. HORNBELK, of Charleston, S. C., presented some vital statistics from the Southern States, showing the death-rate among the colored population to be much greater than that of the whites, and offered a resolution asking the governmental statisticians in preparing their reports to arrange them so that this fact may be shown. No action was taken on the resolution.

#### EVENING SESSION.

At this session appropriate addresses were delivered by GOV. DAVID R. FRANCIS, of Missouri; GOV. L. U. HUMPHREY, of Kansas, and the HON. JOHN T. PEAK, of Kansas City, Mo. Following these came the

#### PRESIDENTIAL ADDRESS

by DR. FREDERICK MONTIZAMBERT.

Dr. Montizambert said, to the medical men of Kansas City and vicinity the meeting was meant in part as an appeal to quicken interest in the more purely preventive work of the profession, to increase interest in the organization and working of the coast quarantines and health boards by which people are affected; the sewerage of cities; the disposal of garbage and refuse; the purity of water-supply; the infectious diseases of animals now known to be closely related to those of man, as well as other much broader questions of modern sanitation.

To the non-medical of all ages, sexes and conditions it is an appeal to take a lively and an active part in the great crusade against dirt and disease. In the words of Sir Spencer Wells, "Instruct your mayor and corporation, your clergy, and your own household, that every case of typhoid fever or scarlatina, of diphtheria or small-pox, of measles or whooping-cough, can no longer be looked upon as natural and providential; but that the existence of such preventable diseases is a proof of ignorance and negligence, and a disgrace to the country, to the town and the family."

Every one can do a little to make one home or one room bright, more cleanly and more wholesome. Sunlight, pure air and thorough cleanliness are natural enemies to disease germs. These cannot live where they have not their proper food, which is found in dampness, darkness, mould and dirt. There is no sounder philosophy than the old saying that, "There is more health in a sunbeam than in drugs, more life in pure air than in a physician's skill, and that sunlight may fade your carpets, but better that than have its absence fade your cheeks."

The President then paid a tribute to the memory of such members as had died since the last annual meeting. He then passed in review the various contagious diseases as battled with by the health authorities of the country, together with the experiments entered into to overcome them. Asiatic cholera, influenza,

cancer, and diphtheria were all touched upon, as well as disinfection and immunity.

#### SECOND DAY.—MORNING SESSION.

DR. PAUL PAQUIN, of Battle Creek, Mich., read a paper on

#### VACCINE AND VACCINATION.

Dr. Paquin touched first upon the necessity for absolutely pure vaccine, and told of some of the diseases that accrue from impure vaccine. The doctor had tested on rabbits, guinea-pigs and fowls over one hundred vaccine specimens. In these tests he said he had found such forms of bacteria as the bacillus pyogenes foetidus, the staphylococcus pyogenes aureus, the bacillus septicus, and gangrene micrococci. These, he said, produced abscesses, gangrenous lesions, septicæmia and pyæmia.

DR. CHARLES N. HEWITT, of Red Wing, Minn., spoke of unfavorable results from using bad vaccine in his State and of the difficulty in obtaining good vaccine, and gave his personal experience.

DR. YESI, of Mexico, spoke of compulsory vaccination of Mexico. Human vaccine alone was used. Lower animal vaccine is not cultivated. Better results from human than animal vaccine are obtained. A serious small-pox epidemic has not visited that country in about twenty-five years.

DR. L. F. SOLOMON, of New Orleans, La., replied that in Louisiana each child must show a vaccination certificate before being allowed to attend school. About fifty per cent. of the primary vaccinations were successful. He favored the use of bovine virus.

DR. DELOS FALL, of Albion, Mich., read a paper on

#### THE DISPOSAL OF GARBAGE AND REFUSE.

He spoke of the intimate relation between typhoid fever and the accumulation of waste organic matter. The method used in New York is taking the waste out to sea and dumping it. Philadelphia recommended cremation. Chicago objected to the use of waste in filling vacant lots and then building houses on them. San Francisco recommends cremation. Baltimore has dumps, which are objectionable, and which will be removed as soon as a better method can be found. Cincinnati gives its waste to a desiccating company, which is under contract to remove the same. In Charleston the city removes its own garbage; carts it out in the morning, and generally gets through about noon. This waste is dumped into a salt-water marsh. The cost is about \$19,000 a year. Milwaukee pays \$23,316 a year for collecting garbage by hand, and \$15,000 a year for disposing of the same. The Merz system of disposal of the garbage is used. Garbage is at present disposed of by dumping it into Lake Michigan, much to the disgust of the citizens, because the Merz system contract has expired. In Washington the removal is carried on by the contract system.

DR. EDWARD CLARK, of Buffalo, New York, made a report on the collection and transportation of garbage and refuse in cities. He advised full police power for the sanitary officer of large cities. A galvanized-iron tank holding about two or three bushels is the best receptacle for holding household garbage. The refuse tank must not be placed on the street or sidewalk, but the collector should be compelled to go in and get it, remove the contents and replace the cover. For transporting, garbage carts are preferable for

short, and wagons for long hauls. The beds should be made water-tight and should be flushed after each dumping. Any driver who failed should be instantly discharged. The bed should be covered with iron.

#### EVENING SESSION.

The first paper was upon

#### RABIES,

by DR. J. J. KINYON, of the United States Marine Hospital Corps. He said the disease was transmitted almost wholly by the canine and feline species. The disease prevails all over the world, except in Australia, where it is not known. He regretted that so little was known of its prevalence. He opposed the idea that the disease is confined to warm weather, the statistics showing that the greater number of cases occur in December and May. He discussed Pasteur's system and its success. Recognition of the disease is not easy in any animal in the early stages. He advocated the establishment and enforcement of strict quarantine regulations in order to eradicate the disease.

DR. P. C. REMONDINO, of San Diego, Cal., read a paper on

#### AMERICAN CLIMATES AND THEIR PHYSICAL EFFECTS.

He said that it is well known that European immigrants soon lose their ruddy cheeks and bright eyes, with a certain loss of spirits, when they come to this country. They live in happy disregard of all hygiene or science. In changing climate they followed no national rule whatever for the really necessary change of diet. He then extolled Southern California and compared it to the Garden of Eden.

A paper on the subject of

#### ANIMAL DISEASES,

was read by MR. ERNEST L. DUNDAS, United States veterinary inspector at the Kansas City packing-houses. He spoke strongly against the evil of diseased cattle being shipped to market. As soon as a farmer discovers that tuberculosis is about to ravage his cows, he immediately ships them off to market to get rid of them before they die on his hands. He recommended the police supervision of all milk dairies.

DR. WALTER D. GREEN, of Buffalo, said that, while it might not be incorrect that the disease was quite common and deserved close watching, still the fact should only urge the physician to more earnestly fight against the spread of disease among his patients.

DR. PETER BRYCE, of Toronto, limited his remarks to tuberculosis in milk, and the manner in which the disease is most commonly transmitted to consumers. In Canada, he said they never breed their milk cows, and in one city they never use a milk cow after she once goes dry; she is immediately sent to the butcher.

The great question is how to tell a cow when she is so afflicted. It seemed to him that in view of the startling figures that there are 15,000,000 cows daily supplying the country with milk, and the fact that in certain abattoirs it has been shown that five to ten per cent. of the cattle killed are tuberculous, there should be a most rigid and regular inspection of all milk cows, as is due the public.

#### NEW ORGANIZATION OF THE SUPREME BOARD OF HEALTH OF MEXICO,

formed the theme of a paper submitted by DR. DOMINGO ORVANANOS, of the City of Mexico. In this

paper the outline of work covered by the Mexican Supreme Board of Health was given, showing a most complete system of supervision, a system which on its face would tend to make it one of the most thorough in operation in any country. One exceedingly good feature is the sending of a surgeon-physician with every ship leaving Mexican ports, who shall be held responsible for the sanitary condition of the vessel, and who shall be obliged to report to the Mexican consul at every port where the vessel may touch, and obtain from him a clean bill of health. This move was done in view of the fact that Mexico is preparing to meet the reciprocal treaties of all countries, thus calling for the service of an extensive maritime navy.

The session was brought to a close by a paper entitled,

LAND HABITATION AS A PUBLIC HEALTH MEASURE, read by DR. GEORGE HOMAN, of St. Louis, Mo.

The paper showed the benefits which would arise by the individual ownership of homes, as that would render less likely any communicable disease as well as render easier the fight against disease by admitting of isolation, a most desirable feature in combating disease.

#### THIRD DAY.—MORNING SESSION.

DR. PETER H. BRYCE, of Toronto, read a paper entitled,

THE PRESENT POSITION OF THE MILK-SUPPLY PROBLEM FROM THE PUBLIC HEALTH STANDPOINT, AND SOME PRACTICAL METHODS FOR SECURING SAFE PUBLIC SUPPLIES.

Briefly, the summing up of the precautions necessary to healthy milk were:

(1) It is especially desirable that a system of periodic veterinary inspection be exercised in addition to the dairyman's inspection.

(2) Strong views should be held and exercised regarding the nature and quality of food for cows. All decomposed foods, as those which are liable to undergo fermentation, should be wholly avoided. The best foods are well ripened grains and grasses.

(3) The stables of the cows are a point of great importance. Too often dark, damp, ill-ventilated and crowded pens have been the home of this chief of our food supplies. It is quite possible to keep, even on a large scale, a dairy stable free from the ordinary disagreeable stable odors. The water-supply to the cows is of equal importance.

(4) The care of the milk at the time of taking and subsequently is of all points at once the most difficult and the most necessary to supplying a wholesome milk. De Claux has said, "Cleanliness is everywhere the *sine qua non*." This means almost a revolution amongst farmers and dairymen. The sterilizing of all cans and bottles by steam or dry heat and the boiling of all strainers will be necessary.

(5) The delivery of milk is of prime importance.

(6) When milk has reached the consumer, it must be placed in a refrigerator or promptly consumed.

#### FOURTH DAY.—MORNING SESSION.

DR. J. RAMON YCAZA, of the City of Mexico, read a paper entitled,

A FEW CONSIDERATIONS UPON THE PROGRESS OF PUBLIC HYGIENE.

DR. NAZARIO LOMAS, of Morelos, Mexico, followed with a paper entitled,

#### NOTES ON THE HYGIENE OF RICE CULTURE.

Morelos is the great rice-producing State of Mexico, and the paper touched upon the sanitary effects of this culture. The vast rice swamps were declared by the author to be most unsalubrious.

The report of the Committee on

#### CAR SANITATION,

was read by PROF. W. W. DANIELLS, Chairman.

He said the great difficulty in the heating arrangements of cars was that all systems thus devised are for heating alone, and that ventilation is not particularly sought.

DR. R. HARVEY REED, of Mansfield, O., said that if the public asked for these things, as it demanded fast trains and elegant upholstered cars, it would get them.

PROF. DANIELLS thought that cars should be made differently. Instead of covering Pullman cars with expensive tapestry they should be furnished with rattan or leather, as, for instance, the cars on some of the suburban trains.

DR. JOSEPH SHARP recommended comfortable air cushions that could be taken out and cleaned.

DR. CHARLES N. HEWITT, of Minnesota, read a paper on

THE EXISTING METHODS OF DEALING WITH IMMIGRANTS AS RESPECTS INFECTIOUS DISEASES IN ENGLAND AND ON ENGLISH SHIPS.

The notification of infectious diseases among immigrants to the United States was the duty of the national sanitary authorities to the sanitary service of the State, and an example of such an arrangement between the United States authorities and the State Board of Health of Minnesota, was cited.

DR. A. N. BELL, of Brooklyn, followed with a paper on

#### THE BATH AND ITS ADOPTION.

The Executive Committee reported to the Association two resolutions which were passed. One was by Dr. Homan, of St. Louis, declaring it the sense of the Association that State and Provincial inspection of the production of vaccine virus be established. The other resolution asks the establishment of a Federal Department of Health, to have at its head a Secretary of Public Health—a cabinet officer at Washington.

DR. HENRY B. BARKER, of Lansing, Mich., introduced a resolution to the effect that the Association hold its meeting in 1893 in the City of Chicago, and that, so far as possible, the occasion be made an international congress of hygiene and public health; which was adopted.

The following officers were elected for 1892: President, Dr. Felix Formento, New Orleans, La.; Vice-Presidents, Drs. Walter Wyman, Washington, D. C., and Domingo Orvaquero, of Mexico; Secretary, Dr. Irving A. Watson, Concord, N. H.

Place of meeting, City of Mexico; date to be fixed by the Executive Committee.

ST. MARK'S HOSPITAL, NEW YORK.—The reading given by Sir Edwin Arnold in aid of this hospital realized the sum of \$1,203.73.

# SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

G. H. MONKS, M.D., SECRETARY.

MEETING Wednesday, May 6, 1891. DR. A. T. CABOT in the Chair.

DR. CABOT reported

THREE CASES OF COMPOUND FRACTURE OF THE PATELLA, IN WHICH THE BONES WERE WIRED WITH GOOD RESULTS.<sup>1</sup>

DR. J. C. WARREN said: I have been somewhat interested in this operation myself. I am inclined to agree with Dr. Cabot that one is not justified in opening the knee-joint in a case of simple fracture, for I think that it is not necessary. I have had a little experience with Malgaigne's hooks and needles, which can be passed through the tendon on either side of the patella above and below. Wyeth's modifications of Malgaigne's hooks are a great improvement over the instrument with which we are familiar in the text-books. With antiseptic precautions the instrument can be adjusted without ether, with a little cocaine above and below the bone, and then drawn together with a screw, and if an antiseptic dressing is applied to protect the points they do not cause suppuration. The cases in which I had the opportunity of trying the treatment were not suitable cases. They were cases of old fracture. The fragments came together perfectly well but did not hold together well afterwards. The one case I followed up afterwards came to wiring. It was done by Dr. Richardson a year afterwards, and the result was very satisfactory although the wires did not remain in. The silver needles also worked very well, and brought the fragments nicely together. The cases in which those needles were used I have not followed up since they left the hospital. I did not think at the time that bony union would be obtained because the fractures were somewhat old at the time the needles were used, but the interesting part in those cases was the fact that apparatus of that kind could be used to approximate the fractures without bringing on any disagreeable complications, and in a fresh fracture I should think they would be almost as efficient as wiring, therefore they would be suited to cases of simple fracture if it were desired to use them for that purpose.

The other day I was called to the hospital to see a case of compound fracture of the patella into the joint. There was a very small opening not much larger than would admit the forefinger, but on laying open the skin, and enlarging the wound through the skin a somewhat larger subcutaneous wound was found, and below that was about a quarter of the patella on the right-hand upper corner which was separated, and when the joint was pressed blood oozed up through the wound in the bone. I washed out the joint with a weak solution of corrosive sublimate, and wired it pretty much after the method Dr. Cabot described first, and hammered the wire down and cut it off. The patient had a slight aseptic fever lasting about two or three days, and is making an uninterrupted recovery. It is now about two weeks since the operation.

OPERATION FOR THE RELIEF OF A VERY SEVERE FACIAL NEURALGIA.

DR. S. J. MIXTER showed a patient sixty-three years of age, on whom he had operated twelve days before,

removing both the second and the third divisions of the fifth nerve through the same external incision, at the foramen rotundum and foramen ovale respectively. There had been no pain and the wound had healed without suppuration. This is the second case operated on by Dr. Mixter in this manner.

DR. MONKS showed some

FRAGMENTS OF GLASS REMOVED FROM THE POPLITEAL SPACE WHERE THEY HAD LODGED FOR OVER THREE YEARS.<sup>2</sup>

DR. J. C. WARREN reported

TWO CASES OF AMPUTATION AT THE HIP JOINT,<sup>3</sup> and showed one of the patients operated upon.

DR. NEWELL: I would like to ask if in this case there was any apparent cause.

DR. WARREN: I don't remember. It dates back some ten years.

DR. NEWELL: It was not necessarily of tuberculous origin?

DR. WARREN: My impression is that it was of tuberculous origin, although I find that no microscopic examination was made of the bone at the time to identify tuberculous condition. It was a disorganized knee-joint. I assumed it was tuberculous.

DR. NEWELL: I think this case is a very important one, as showing that a surgeon should never lose his courage in the most desperate sort of case that is not malignant. I remember seeing this boy at the time Dr. Warren operated, and it seemed to me the case represented a forlorn hope.

I remember one other case that taught the same lesson, that a surgeon should never fail to do an operation that might do some good. This case came to the hospital while I was house-officer. A boy had a barrel of cider roll on his outstretched arm, and the arm was black and gangrenous. That was in the days of septic cases. The boy seemed almost moribund, and gas had so developed in his sides and under the pectoral muscles that there was perfect crepitation. In that case Dr. Warren thought he could save the boy by making free incisions. The incisions were made and inside of two weeks that boy was walking about the yard.

In reply to a question as to the desirability of leaving behind as much periosteum as possible, in order to cause new bone to form and thus enable the patient to wear an artificial limb, DR. WARREN said that he left considerable periosteum, but he could not say how much. In one of his cases there was considerable new bone formation.

DR. CABOT said that his experience with the operation had been that there was more difficulty in taking away the periosteum than in leaving it; and that the bone in such cases shells out easily and leaves the periosteum behind.

MR. G. R. TRUCKER (by invitation) demonstrated a method of his own for the

STERILIZATION OF CATGUT.<sup>4</sup>

DR. F. M. BRIGGS read a paper on

TORSION,<sup>5</sup>

and showed an automatic forceps, of his own invention, for rapid torsion.

<sup>1</sup> See page 543 of the Journal.

<sup>2</sup> See page 538 of the Journal.

<sup>3</sup> Publication postponed.

<sup>4</sup> See page 541 of the Journal.

DR. WARREN: I can testify to the usefulness of this instrument, having seen Dr. Briggs use it in several operations, the most important of which was in an amputation of the breast, and dissection of the axilla. The disease was very extensive. A large ulcerated mass the size of a fist, was showing on the inner hemisphere of the breast, involving the entire breast besides, therefore a complete amputation of the whole organ had to be performed leaving a large open wound. Then there was a long incision through the axilla with dissection of the axilla, and any surgeon knows how many vessels are wounded during such an operation. There were two arteries only that were tied, and they were down in between the ribs, and could not be got at very well except by a pair of hæmostatic forceps with a sharp nose. There was one large vein I thought more prudent to tie. The little defects in the instrument brought out by the operation seemed to me to be minor ones, and when it is perfected it ought to be quite a useful instrument.

DR. NEWELL introduced the subject of

#### A KIND OF OEDEMA SOMETIMES FOLLOWING THE INJECTION OF COCAINE.

He said: I would like to speak of an experience I had to-day in the use of cocaine. We have been using one per cent. solution of cocaine for small operations, and to-day I removed a small fatty tumor from the forehead. The parts got a little painful during the operation, and I put in a little more of the solution. After the wound, which was about an inch long, had been closed all but one stitch, there developed what I supposed was a hæmatoma, from my needle going through and cutting a small vessel. I put in the scissors and supposed I would squeeze out a clot of blood. Nothing came out, but I saw oozing from the edges of the wound some serum. This was, I suppose, due to vasomotor paralysis after the use of cocaine. It was very striking and very rapidly developed.

DR. MIXTER: A friend of mine, a physician, told me that in using cocaine he has seen an enormous œdema caused almost immediately from vasomotor paralysis. I have never seen a case myself.

DR. J. E. GOLDTHWAIT showed

#### A NEW FORM OF SPLINT FOR THE THUMB.<sup>6</sup>

By means of this splint the thumb could be fixed but motion at the wrist could be allowed.

DR. H. L. PERRELL said that he had used the splint in practice and had found it one of the most satisfactory devices that had been brought to his notice.

### Recent Literature.

*The Science and Art of Obstetrics.* By THEOPHILUS PARVIN, M.D., LL.D. Second Edition. Philadelphia: Lea Brothers & Co. 1890.

This standard work, which may well be called a classic, first appeared in 1886. The second edition, which was issued late in 1890, has received numerous additions and alterations, but without material increase in size. Fifteen new wood-cuts have been added. From the scientific stand-point the work is sound in its teachings, and the parts on practice are replete with wisdom and common-sense. Altogether, it is a book of which its accomplished author may well be proud.

*A Text-Book of Chemical Physiology and Pathology.* By W. D. HALLIBURTON, M.D., B.S.C., M.R.C.P., Professor of Physiology at King's College, London, etc. With 104 Illustrations. London and New York: Longmans, Green & Co. 1891.

It is now six or seven years since a complete text-book of physiological chemistry has appeared in the English language. During this time great advances have been made in this department, and chemistry at the present day occupies so prominent a place in investigations connected with the causation and treatment of disease, that the importance to the medical student of a knowledge of this subject, and particularly of physiological and pathological chemistry, is unquestioned. Dr. Halliburton's book, which is one of unusual excellence, comes to us therefore at a very opportune time.

Part I, which is devoted to Methods of Research and Analysis, contains a short sketch of the chief operations performed in chemical investigation, those specially available for physiological work being dwelt on rather more fully.

In Part II, the Chemical Constituents of the Organism are described. This division of the book contains a short chapter on inorganic compounds, one on the simpler organic principles, and chapters on the carbohydrates, proteids, albuminoids, ferments and fermentations, pigments, ptomaines and leucomaines.

In Part III, which is devoted to the Tissues and Organs of the Body, the author discusses, in order, the cell, the blood in health and disease, the blood of invertebrate animals, the lymph and allied fluids, respiration, muscle, epithelium, the connective tissues in health and disease, the nervous system, and the organs of the body.

In Part IV, Foods, and the Chemical Processes concerned in Digestion, Absorption, Assimilation, and Nutrition are described; and in Part V, the Urine, and the Secretions of the Skin and Allied Structures. Under the head of General Metabolism, in Part VI, the chemical exchanges which occur in living tissues are considered in their relation to one another.

The book contains 852 pages full of information, 104 illustrations, several hundred references to original sources of information, and, what is by no means a trifling matter, a good index. It supplies a want long recognized, and will be highly valued by all who are interested in this department of science.

*The Medical Student's Manual of Chemistry.* By R. A. WITTHAUS, A.M., M.D. Third edition. New York: William Wood & Co. 1890.

The principal changes in this edition are to be found in that portion of the work which treats of the principles of chemistry and chemical physics, which has been somewhat extended; and in the chapters on the chemistry of the carbon compounds, which have been in great part rewritten. The orthography of certain words has been modified in accordance with the views expressed in the report of the committee of the Chemical Section of the American Association for the Advancement of Science. The report of this committee is printed in full in an appendix. The present edition is a distinct improvement over the preceding one. The book has been prepared solely for the use of medical students, and we consider it, after several years experience with it in the class-room, the best one to recommend to such.

THE BOSTON

## Medical and Surgical Journal.

THURSDAY, NOVEMBER 19, 1891.

*A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.*

**SUBSCRIPTION TERMS:** \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,  
283 WASHINGTON STREET, BOSTON, MASS.

## THE SURGERY OF THE LIVER.

THE surgery of the liver has made signal progress of late years under antiseptic methods, and now operations which a generation ago were not thought of, are daily performed. Abscesses are freely opened, and hydatid cysts punctured, and resection of considerable portions has in some instances been done; the gall-bladder has been now hundreds of times opened for the removal of calculi, and impacted stones have been removed from the cystic and choledochus ducts by crushing or by cutting. Cholecystectomy, or extirpation of the gall-bladder, though not a very feasible operation, has in several cases been done successfully.

We are indebted to Lawson Tait and Langenbeck for the earliest operations on the gall-bladder. Up to October, 1884, cholecystotomy, or incision of the gall-bladder for obstructive diseases of that vesicle and its ducts, had been performed thirty-five times with a mortality of ten (see paper by Musser and Keen in the *American Journal of Medical Sciences* for October, 1884). In discussing the various methods of operating, Dr. Keen, in the article above mentioned, expresses a preference for the oblique-transverse incision parallel to the right costal margin, and this is also the method advocated by Terrillon, who gives notes of five successful cases in the *Bulletin Général de Thérapeutique*, February 15, 1891. It is needless to say that the vertical incision over the site of the gall-bladder, as advised by Jamnaway, is preferred by some surgeons. In the *Edinburgh Medical Journal*, October, 1889, Lawson Tait reports fifty-five operations of the kind; in fifty-two the patients recovered, but the three deaths were from other causes than the operation. At the Clinical Society of London for the same year, Mayo Robson communicated a paper on fourteen cases of cholecystotomy which he had performed, eleven being for gall-stones, one for empyema of the gall-bladder, and two for distended gall-bladder, due to cancer. All the patients recovered. In the *Lancet*, January 10, 1891, Robson reports nine more cases without a death, and strongly recommends the operation whenever

there are repeated attacks of biliary colic apparently due to gall-stones which do not yield to a definite course, not necessarily very prolonged, of medical treatment. The testimony from German and French surgeons is equally favorable to the operation, which, in the estimation of Langenbeck, should always be performed, and that *early*, rather than *late*, when the ordinary medical means fail to cure.

Instead of the usual way of treating the gall-bladder after its incision and the removal of the obstructing calculus, namely, the formation of a biliary fistula by attaching the opening in the bladder to the lips of the wound in the abdominal wall, cholecystenterostomy, first proposed by Nussbaum, is sometimes practised. The small intestine is opened at the highest point below the duodenum, and the margins of the opening in the gall-bladder are attached to the edge of the opening in the bowel. This operation was first successfully performed by Kappeler, afterwards by Wiuiwater, and has lately succeeded in the hands of Socin. It was a case of obstruction to the ductus communis choledochus. A free incision was made along the border of the rectus. The peritoneal cavity was opened, the gall-bladder drawn forward, opened, and a pint of gall evacuated. A cholecystenterostomy was then determined upon. The jejunum was drawn out, an incision an inch and a quarter long made in it, and this opening sewed to that in the gall-bladder. The result was most gratifying.<sup>1</sup> Mayo Robson also successfully operated in the same way for biliary fistula in March, 1879.

There has been considerable discussion as to when cholecystectomy should be preferred to the simple incision of the gall-bladder and the creation of a fistula (which is generally only temporary), and it may be said that no general rule can yet be laid down. The surgeon, as Terrillon says, should be guided by the nature of the lesion. Lawson Tait declares cholecystectomy preferable in the great majority of cases, and with this most authorities agree. Cholecystectomy demands a certain number of conditions rarely realized; in fact, if the gall-bladder and cystic duct are inflamed and adherent to the hepatic tissue, if this duct, dilated by calculi, is, so to speak, incrustated in the liver, the sac can neither be safely extirpated, nor made to terminate in the intestine. The case is the same when an antecedent inflammation has glued the surface of the gall-bladder to the neighboring parts (Terrillon). Mayo Robson would limit cholecystectomy to cases of contracted gall-bladder which cannot be sutured to the parietes, or where perforation from ulceration has occurred, or in empyema where the tissues are thin and unable to bear suture; also where, after a cholecystotomy, a mucous fistula persists, owing to stricture of the cystic duct.<sup>2</sup> This writer finds cholecystectomy ordinarily so simple and safe an operation, that he would have little patience with a physician who, in a case of repeated attacks of biliary colic did not resort to it.

<sup>1</sup> *American Journal of Medical Sciences*, October, 1888, p. 418.  
<sup>2</sup> *International Clinician*, April, 1891.

With regard to lithotripsy, this is sometimes feasible where during an operation, the cystic duct or choledochus is found occluded by a stone; if this be soft it may be crushed between the thumb and finger, or if rather hard, the crushing may be performed with guarded forceps, and the fragments by digital manipulation are made to pass into the gall-bladder where they are readily removed.

The liver has been often opened for abscesses. A sufficiently deep, free incision is made under antiseptics to evacuate the pus, and the abscess sac is washed out every day by antiseptic lotions.

Exploratory punctures into the substance of the liver by means of the aseptic aspirator needle are made with safety, and the presence of hydatid cysts may be thereby determined. Terrillon cites the case of a man who had several hydatid cysts in the liver and in whom he practised successively, at varied intervals, more than sixty exploratory punctures with the Dieulafoy needle. The patient got well after the opening and antiseptic lavage of three large pouches occupying divers regions of the liver.<sup>2</sup> Exploratory incisions, after a laparotomy made for this purpose have also been effected, and deep abscesses have thus been reached and drained.

As for that rare and formidable operation known as resection of the liver, or rather, of portions of the liver, there are a few instances on record where such ablation has been performed with varying success.

Naturally the surgeon would be deterred from excision of part of so vascular an organ by the difficulty of controlling hæmorrhage. Langenbeck, in fact who was one of the first to attempt so hazardous an operation, came near losing his patient by secondary hæmorrhage, though the lobe which he removed was distinctly pediculated, and Wauger (Nineteenth Congress of the German Society of Surgery, 1890), had a similar case which proved fatal. The operation was the section and firm ligature of a pediculated lobe of the liver which had undergone alterations due to syphilis. At the end of twenty-four hours, the patient died from hæmorrhage by giving way of the friable tissue of the pedicle.

Lawson Tait, on the other hand, reports several cases where he has successfully removed parts of the liver; he always takes the precaution to touch the surface of section with a solution of perchloride of iron.

Terrillon cites from the *Bulletin Médical*, December 10, 1890, a case of ablation of a gummy of the liver. The operation was performed by Hochenegg, a Hungarian surgeon. The tumor, which was as large as an apple, was seated beneath the false ribs and was very painful; it was removed by laparotomy. Hochenegg divided the hepatic tissue by the thermo-cautery. Despite this precaution, there was considerable oozing of blood, necessitating tamponading with iodoform gauze. The tampon was fixed to the anterior part of the abdomen by means of a steel rod.

Terrillon reports a successful case of his own, which he describes as "ablation of a portion of the liver full of hydatid cysts." It was a cystic tumor of the liver, hard, painful, fluctuating, and projecting seven centimetres below the costal margin. The abdomen was opened by a transverse incision, fifteen centimetres in length, parallel with the lower border of the false ribs; a tongue of liver projected into the opening; the most prominent portion, which corresponded to the hydatid tumor, was seized with a Nelaton forceps, and a strong rubber band two centimetres in diameter was passed around the base and knotted as tightly as possible, the knot being secured by a stout silk ligature. This elastic band was seen to produce by its constricting power a veritable furrow in the hepatic tissue, completely isolating the diseased segment. This was now brought out of the abdominal wound and fastened outside, very much like the pedicle in ovariectomy; the lobe thus ligated was about as large as the closed fist. The abdominal wound was now closed by deep sutures, the margins of the flaps being brought tightly around the furrow made by the rubber band so as to shut off the abdominal cavity. The usual antiseptic dressings were now applied. The result was entirely satisfactory.

All the substance external to the elastic ligature soon became sphacelated and shrunken. On the fifth day, the rubber band was cut and the necrosed mass dissected out. The peritoneal adhesions proved to be firm; there remained at the site of the wound only a little cup-shaped depression, at the bottom of which appeared the remains of the sphacelated pedicle. The parts were kept disinfected with chloride of zinc and iodoform gauze. In ten days the patient was well.

#### THE NEW YORK WATER-SUPPLY.

THE few hours' rain on the 11th did not have much effect in increasing the Croton water-supply, and unless the rain of Tuesday has made some impression, most serious consequences are likely to ensue in New York, notwithstanding all the efforts that are being made to prevent waste on the part of the public. Already it has been found necessary to greatly reduce the pressure in the pipes, and in consequence the water does not run at all on the upper floors, except where the houses are provided with tanks and pumps, in many parts of the city. The whole trouble arises from the fact that while ample facilities have been provided, by means of the two aqueducts now in operation, for conveying water to the city, no adequate provision has, as yet, been made for permanent storage of the water-supply. The supply of the Croton water-shed is entirely sufficient for the needs of New York for many years to come, being equivalent to about 300,000,000 gallons a day for the entire year. Since the new aqueduct was opened the amount delivered has been at no time over 165,000,000 gallons, and it has been calculated that the present requirement of the city under full pressure and with no stint upon the supply would be at most 200,000,000 gallons daily.

<sup>2</sup> *International Clinics*, April, 1891.

While, however, the aggregate annual flow of the Croton water-shed is equivalent to 360,000,000 gallons a day, it is very fluctuating, and what is needed is simply a system of storage reservoirs adequate to receive the surplus of wet times and hold it against periods of light rainfall; so that the supply may be equalized throughout the year and delivered through the aqueduct without diminution of the daily flow. This should certainly have been carried out before this, as it is now eight years since the legislature passed the act providing for an increased supply of water for the city, and this included not only a new aqueduct to convey the water, but also for the construction of one or more dams and reservoirs to retain such water. While several storage reservoirs have been planned and are either completed or in course of construction, the engineers have shown that no adequate provision can be made under the circumstances without the erection of a high masonry dam, above the old Croton dam, and it seems probable that the present threatened water famine will stimulate the authorities to commence the work at once.

#### MEDICAL NOTES.

**THE NEW YORK PRACTICE LAW.**—The Attorney-general of New York, has decided that by the law which has recently gone into effect, all physicians having foreign diplomas only, and desiring to practice in the State, must undergo an examination by the State Medical Board before a license can be issued.

**THE DUTY ON OPIUM.**—The present duty of twelve dollars a pound on opium, is such an inducement to smugglers that they are taking every sort of risk on the Canadian frontier, and are spreading demoralization among the United States agents by the big bribes which they are able to offer to get it through. It is believed that an attempt will be made as soon as Congress meets to reduce the duty to perhaps two dollars.

**COLORIED FEMALE PHYSICIANS.**—The *Medical Record* of November 7th contains a remarkable letter from Dr. Reyburn, of Washington, in which he offers documentary evidence that the Medical Department of Harvard University is in the habit of graduating colored female physicians. We are authorized to state that no woman, of any color, has ever graduated from this school. Another error appears in the statement that the three years' graded course was established in 1879; whereas it went into effect in 1871-72.

**WASHINGTON WATER.**—Dr. Weir Mitchell, in a letter to the *Medical News*, says that as he considers Washington the best place for meetings of the Congress, he wishes to defend the water: "The water was not to blame. I drank no drop of it, except as it was used boiled in coffee. I know of others who suffered despite this and every other precaution; also, manifestly was too general to have been due to food, for it affected people living in hotels and in private houses.

Finally, it existed over a large part of the country—in Newport, R. I., for instance, whither I went after a week in the Maryland hills, where also it was sharply felt. The cause, therefore, was not the product of Washington, nor should it be allowed to influence us when again we come to summon, for a like purpose, the remarkable body of men which constituted the Congress."

**THE NEW YORK JOURNAL OF GYNECOLOGY AND OBSTETRICS.**—Under this title a new monthly journal appears this month for the first time. It is edited by Drs. A. H. Buckmaster and J. D. Emmet, with the collaboration of Drs. T. A. Emmet, T. G. Thomas, A. J. C. Skeue, C. Jewett, W. H. Baker, E. C. Dudley H. A. Kelly and J. C. Reeve. The object is to give the profession a journal of the highest grade, treating of the title-subjects or allied matter, to contain original articles, society reports and reviews. The opening number contains a very good likeness of the late Dr. Barker, with an obituary notice.

**THE TEXAS SANITARIAN**, a monthly journal of preventive medicine and hygiene, appears for the first time with the November issue. It is published at Austin, Texas, under the editorship of T. J. Bennett, M.D., and contains seventy-two pages of interesting reading matter.

**AN INFIRMARY FOR PRINCETON COLLEGE.**—President Patton and a committee of the faculty of Princeton College have sent circulars to the alumni and friends of the college showing the needs of an infirmary for the university and soliciting subscriptions. A site on the college grounds has been set apart, and the plans of the building, drawn by Surgeon J. S. Billings, have been adopted by the committee. The building will be constructed of brick, containing accommodations in wards and single rooms for twenty patients, with all modern hospital arrangements. It will cost \$30,000, in addition to which an endowment of \$20,000 is proposed to pay running expenses, and that poor students may receive its benefits free of charge.

**THE PROSPECTS OF A MEDICAL MAN IN AUSTRALIA.**—The editor of the *Australasian Medical Gazette* warns medical practitioners in the older countries that Australia is over-supplied with medical men, and that the proportion in relation to the population is probably greater than in England. Certain disappointment, perhaps great poverty and distress, inevitably await a medical stranger who goes to those colonies without intimate connection with influential residents, unless he has ample means. It should also be remembered that the prizes there for the best men are nothing like equal to those in capital cities of the United Kingdom. Any vacancies in the junior ranks are at once filled by graduates of the local schools.

#### NEW YORK.

**THE STEAMER "ALLIANCA"** which arrived from Brazil on November 12th, had a somewhat eventful passage. On October 14th she sailed from Santos, where yellow fever was epidemic at the time, and two

days after leaving Bahia, the ship's surgeon, Dr. H. R. Rosenthal, died of the fever and was buried at sea. Dr. Rosenthal was a young New York physician, and was making his first voyage in the capacity of ship's surgeon. Although ill himself, he had been most assiduous in his attentions to several of the crew who developed yellow fever before reaching Bahia, and who were transferred to the hospital at that place. After Dr. Rosenthal's death three others of the crew were taken with the fever, and two of them died before the vessel reached Barbadoes. Here a new surgeon was obtained, Dr. Homer Clark, and soon after the *Alliance* left that port, which was on the 5th of November, the third man died and was buried at sea. Every precaution to prevent the spread of the disease was taken, and none of the passengers were taken with it. When the ship reached the New York Quarantine there was apparently no yellow fever on board, and she was allowed to proceed to her dock in Brooklyn. Shortly after landing, however, it was discovered that the ship's barber was suffering either from malarial or yellow fever, and he was sent to the hospital for contagious diseases at Flatbush. According to the latest accounts, the diagnosis was still somewhat uncertain, and the case did not seem to be a very severe one; but the ship was again thoroughly fumigated before the unloading of her cargo was permitted.

**BATHS FOR THE POOR.**—During the past week some cheap baths have been opened to the public by the managers of the Hirsch Fund in New York. As in the People's Baths recently established by the Association for Improving the Condition of the Poor, the rain or shower bath is employed, and the prices for a bath are three and five cents.

**THE CHARITIES REVIEW.**—The first number of the *Charities Review*, which is to be the organ of the Charity Organization Society, has just been issued in handsome form by the *Critic* Company, and contains a number of valuable articles. Among these are papers by Dr. Alfred Shaw on Municipal Lodging Houses; by Myer S. Isaacs, President of the Trustees of the Hirsch Fund, on the work that has been accomplished during the past year through the liberality of Baron Hirsch; by Dr. Edward Everett Hale, on the Prevention of Pauperism; and by Warren Spalding, Secretary of the Massachusetts Prison Association, on the Massachusetts Drunkenness Law. The *Review* is to be published monthly from November to May.

**THE NATIONAL ACADEMY OF SCIENCES** held its annual meeting at Columbia College, on November 10th, 11th and 12th. On the evening of the 10th President Low, of Columbia, gave a reception to the members, and the second evening, Mrs. Draper, widow of the late Prof. Henry Draper, entertained them at her house, where Professor Pickering, of Harvard, gave an account, illustrated by stereopticon views, of the work in astronomical photography, which is being done under the Henry Draper Memorial Fund.

## Miscellany.

### THE NEXT INTERNATIONAL MEDICAL CONGRESS.

At the recent meeting of the Italian Congress of Internal Medicine initial arrangements were made for the next International Medical Congress, which is to meet in Rome, in 1893.<sup>1</sup> In what month of the year it will be held is an important question not yet decided. At midsummer, or in the early autumn, Rome is not likely to be found attractive to those who dread subtropical heat in a malarious vicinity. If held in the spring, or the late autumn, many teachers of medicine will not be able to attend. The last fortnight of September is what the majority of Italian practitioners would suggest as the most convenient time for all parties, and this will most probably be the decision of the Organizing Committee. Meanwhile, that committee has just been formed. Dr. Baccelli, at a meeting of the heads of the profession, was nominated President by acclamation. On his declining the honor, the question was put to the vote, when, out of a ballot of twenty-six, he obtained twenty-five "si," as against one "no," which was himself. He had, therefore, to bow to the overwhelming importunity of his colleagues. The post of General Secretary fell, almost unanimously, to Professor Maragliano, of Genoa. Presidents of the various Sections were next elected. These Sections are twelve in number; and, as the results of the various ballots, the following gentlemen were appointed: Anatomy, Professor Antonelli; Physiology, Professors Albini and Albertoni; Pathology, Professors Bizzozero and Foà; Pharmacology, Professor Cervello; Clinical Medicine, Professors Baccelli, Maragliano, Murri and Bozzolo; Surgery, Professor Bottini; Obstetrics, Professor Morisani; Psychiatry, Professors Morselli and Tamburini; Ophthalmology, Professors Devincenti and Secondi; Dermo-Syphilopathy, Professors Campana and Barduzzi; Forensic Medicine, Professor Tamapia; Hygiene, Professors Pagliani, Celli, and Canalis. The importance attached to this great medical parliament is already apparent in the number of physicians and surgeons who have intimated their intention to assist.

### ENGLISH DEGREES.

The various degrees which carry with them a license to practise medicine in the United Kingdom, are a bewildering to many Americans. The title "Doctor" is supposed to indicate the degree of M.D., given by the universities; but this title is often used by courtesy to men holding the lesser university degree of M.B. The Society of Apothecaries grants the degree of L.S.A., and this is generally considered the lowest degree allowing the holder to practise. The most puzzling degree-conferring bodies to the foreigner are the royal colleges. These are in London, Edinburgh and Dublin. The colleges in London are described by Dr. Winslow Warren,<sup>2</sup> of San Francisco, who has taken the degrees M.R.C.P., M.R.C.S. L.R.C.P. and L.S.A.

The colleges are not teaching institutions, their charters being to grant diplomas. The medical schools

<sup>1</sup> *Lancet*, Oct. 10th 1891.

<sup>2</sup> *Pacific Medical Journal*, September.

in connection with the different London hospitals, on the other hand, do not grant diplomas.

The Royal College of Physicians of London grants three distinct degrees. Two of these are obtainable by examination, namely, L.R.C.P. and M.R.C.P.; one, the Fellowship (F.R.C.P.), is an honorary degree bestowed on members of at least four years standing who have distinguished themselves in their profession in original research.

An English medical student must pass a matriculation examination in arts and sciences and be registered by the General Medical Council of Great Britain four years, after this year five years, before taking his degree. He must then enter the colleges and hospitals and be "signed up" for the various examinations. For the degree of L.R.C.P., he must pass three sets of examinations, the last four years after matriculation. An American physician holding the requisite requirements, may go up for the examinations without previous matriculation.

The same conditions apply to the royal colleges in Scotland and Ireland, excepting that women are admitted to the examinations in Scotland and Ireland, but not to those in London.

The examination for the M.R.C.P., of London, is one of the highest and most difficult in Europe. The candidate must have attained the age of twenty-five years. He must first pass the L.R.C.P. examination or possess an equivalent qualification. He must possess an arts degree or pass an additional examination. He then must go through the ordeal of a two days' written and a third day practical examination in a hospital, and then a fourth and fifth day of oral examinations. It would seem that this degree (M.R.C.P., Lond.) is difficult to obtain, as there are only three American gentlemen who have received it on American diplomas.

The Royal College of Surgeons grants two qualifications: the membership (M.R.C.S., Eng.), and the fellowship (F.R.C.S., Eng.). Two examinations are held for the M.R.C.S. The first one in twenty-four months after matriculation, and the second in four years (five years after 1891). The fellowship examination is very difficult. A candidate must first be an M.R.C.S., and pass examinations in higher branches of physiology, anatomy, and different branches of surgery. An M.R.C.S. may also be made an honorary F.R.C.S. after twenty years.

The Conjoint Board of the Royal College of Physicians of London and the Royal College of Surgeons of England grants the L.R.C.P. of London and the M.R.C.S. of England. The board is composed of members of both colleges. The "examination hall" is a spacious building overlooking the Thames. Its interior is divided into immense halls, where the examinations are held. The laboratories and museums are replete with all the latest appliances and specimens, macroscopic and microscopic, chemical and analytical, etc. This double qualification is the one taken by nine-tenths of the medical men in England. It comprises three examinations. Prior to 1891 the first examination was taken after twelve months, the second

after twenty-four months and the final or pass, after four years from registration. Now the time is five years. The examinations are partly written, partly *viva voce*, partly clinical and partly microscopic and chemical. They are held four times yearly, January, April, July and October. At each of the examinations there are from 250 to 500 candidates presenting themselves.

#### A NASAL SAW.

DR. C. A. BUCKLIN<sup>1</sup> describes this saw as the result of his experience since first introducing this instrument for removing obstructions in the nasal cavity.

The handle is of sufficient size to give one a firm grasp, which is important when the bony deformity is large. Being of aluminium, it is aseptic and light, notwithstanding its size.

This instrument has three reversible blades, six inches long, containing three and one-half inches of cutting teeth. Each blade is designed to overcome special difficulties.

Blade No. 1, or the Bosworth saw, consists of perfectly cone-shaped teeth, thirty to the inch. It is made thin, and binding is avoided by dividing the cutting-power equally between both sides of the teeth.

Blade No. 2, is designed for conditions where it is desirable to cut only as the saw advances. This blade would bind were it not for the fact that the teeth are thirty-two to the inch. They rake sufficiently forward to enable the finger to determine the "rake," as the teeth are drawn over it, while on the return stroke the release is complete.

This blade is very satisfactory for the following reasons: With the head firmly placed against a head-rest, the most natural way to cut with a saw is toward the support. In attempting to remove the inferior turbinated bone entire, the spring of its posterior end frequently causes other saws to bind sufficiently to defeat the operation, which difficulty is not experienced with Blade No. 2. Deformities of the septum which terminate at their posterior end in a delicate ridge will readily catch on teeth which cut on the return, thus springing the septum toward the saw. When this accident occurs a single stroke may cut directly through the septum. These dangers are also obviated by Blade No. 2.

Exceptional conditions may arise where it is desirable to use a saw blade which cuts on the return stroke, this is provided for by Blade No. 3. This blade is

<sup>1</sup> Medical Record, October 24th.

less frequently useful than either of the others. It can only be used on the turbinated bones in rare cases where Blade No. 2, from some accidental peculiarity in the formation of the bone, cannot be used. Peculiarities in the deformities of the septum may present exceptional cases where this blade will work better than the others. It is, however, liable to spring the septum in an undesirable direction, producing accidents already described. Still the instrument would not be universal without this blade.

Operators should not trust the disinfection of a saw to any means less perfect than boiling water.

### THERAPEUTIC NOTES.

**ECZEMA IN CHILDREN.**<sup>1</sup>—In treating the eczema of the face and hairy scalp of fat children Saalfeld recommends that the quantity of nourishment be diminished, and especially that all fatty articles of diet be avoided, constipation being avoided by means of suitable rectal enemata. The crusts which accumulate should be softened with olive oil, and after they have been removed the surface should be anointed with

R Acidul borici . . . . . gr. xx.  
Zinci ox. . . . . 3 l.  
Vaselin. . . . .  
Amyli pulv. } . . . . . aa 3 vi. M.

**THE ABSORPTION OF DRUGS IN THE FORM OF OINTMENTS.**—In the *Répertoire de Pharmacie*, Dr. Luff has published some experiments which tend to show that lanolin is the best ointment basis when a local action only is required, as this substance prevents absorption; whilst vaseline favors absorption, and so should be employed when it is desired to obtain the general action of a drug applied in the form of an ointment to the skin. The experiments were made with iodide of potassium, carbolic acid, and resorcin mixed with vaseline, lard and lanolin.

**QUININE.**—To prevent disagreeable effects from large doses of quinine, Dr. Levi,<sup>2</sup> of Central America, recommends that it be given in the following mixture.

R Quinine sulph. } . . . . . aa 3 l.  
Peppine pore. } . . . . .  
Pulv. capsici . . . . . gr. vi.  
Pulv. zingib. . . . . gr. xij.  
Sodii bicarb. . . . . 3 l. M.

**MASSAGE OF THE STOMACH IN GASTRIC DYSPEPSIA.**—Cseri<sup>3</sup> employs massage in the treatment of gastric dyspepsia. Two or three hours after a full meal, the patient is placed on his back, with thighs flexed and the mouth open. The gastric region is first very lightly stroked, the force then being gradually increased to a kneading, always in a direction toward the pylorus. The whole process should last about ten minutes. A short massage of the large intestine should end the séance. The only contraindication is the existence of complications, such as ulcer or other conditions which may cause hemorrhage. This treatment is said to be followed by a pleasant sense of relief and often by refreshing sleep.

**TO PREVENT RABIES,** Gautier recommends that wounds caused by the bites of animals be immediately and energetically washed out with oil of turpentine.

**TREATMENT OF TYPHOID FEVER.**<sup>4</sup>—M. Hayem gives lactic acid, with or without baths, according to the indications. He prescribes the acid in the form of a lemonade:

R Acidul lactici . . . . . 3 iv-vi.  
Syrup simplicis . . . . . 3  
Aque . . . . . 3 xxvij. M.  
Sig. To be taken in the course of twenty-four hours.

If there is gastric intolerance, the lemonade may be diluted with seltzer-water.

Dr. Tordeus<sup>5</sup> has been applying with considerable success a treatment for typhoid fever in the St. Pierre Hospital, Brussels, which consists essentially of moderate doses of an antipyretic, combined with an antiseptic. Thus, ten grains of acetanilid and an equal quantity of resorcin, or about half that amount of thymic acid, are made up into a five-ounce mixture, with decoction of aloes, and tablespoonful doses administered every three hours. This was found to exert a remarkably beneficial effect not only on the temperature, but also on the general condition of the patients. From trials made with acetanilid alone, it was evident that the antipyretic effect was almost entirely due to the combination with it of resorcin or the thymic acid.
